 - Uncommon lesion most often presenting in childhood or adolescence
 - Predilection for the trunk, particularly paraspinal region
 - Majority (more than 80%) associated with FAP often preceding the development of polyps; considered a sentinel event for FAP
 - Mesenteric Gardner fibroma in FAP referred to as desmoid precursor lesion
- Histologically, poorly demarcated, hypocellular hyaline collagen bundles with artifactual cleft-like spaces, lesional cells have appearance of bland fibroblasts, entrapment of normal tissues (e.g., small nerves, fat, muscle); nuclear positivity for β -catenin; CD34 immunoreactive
- Physical factors:
 - Trauma most often related to surgery may be a contributory factor.

Pathology

Gross

- Firm, tan-white, poorly delineated, or infiltrating lesion of varying size
- On cut section, the lesion has a trabecular or whorled appearance.

Histology

- Poorly circumscribed, composed of uniform-appearing spindle-shaped cells with sharply defined, pale-staining nuclei associated and separated by abundant collagen production
- Cellularity varies but in general only moderately cellular:
 - Cellular variability including hypocellular (collagenized) lesions to markedly cellular lesions.
 - Cells are uniform with tapering or plump-appearing vesicular-appearing nuclei, small nucleoli, indistinct cytoplasm.
 - Lack hyperchromasia, pleomorphism, or mitotic activity
 - Variations of the nuclear appearance may include the presence of stellate-appearing nuclei.
 - Fascicular growth pattern including broad, elongated fascicles; tends to be less well defined as compared with that seen in fibrosarcoma
- Stromal component includes:
 - Variably collagenized
 - May focally be myxoid or mucoid-appearing
 - Some examples may be characterized by the presence of keloid-like collagen or extensive hyalinization.
- Vascularity varies but is generally not a prominent feature:
 - A varying number of blood vessels are present and tend to be more thick-walled than in fasciitis.
 - Characteristic vascularity associated with some sarcomas, including delicate plexiform pattern, is absent in fibromatosis.
- Mild pleomorphism and rare mitotic figures may be identified; atypical mitoses and necrosis not identified.
- Chronic inflammatory infiltrate composed of lymphocytes, plasma cells, and eosinophils may accompany the lesion and varies from being scant to dense in appearance.
- Typically, these lesions are poorly circumscribed and infiltrative along the periphery into striated muscle: at advancing edge of the tumor, lymphoid aggregates and degenerate skeletal muscle cells with bizarre sarcolemmal nuclei are commonly seen.
 - Sinonasal tract lesions may extend into bone.

- Metaplastic components such as bone or cartilage may be present but tend to be focal and not a prominent part of the lesions.
- Histochemical stains of little contribution to the diagnosis
- Immunohistochemistry:
 - Vimentin positive
 - Nuclear β -catenin reactivity:
 - Seen in 70% to 75% of cases, in particular those associated with FAP, but also can be seen in sporadically occurring cases:
 - Not specific as can be seen in lesions other than fibromatosis
 - Variable staining for actins (muscle specific and smooth muscle)
 - Typically negative for S100 protein and desmin, but one or both may be focally present
 - Negative for MUC4, CD34, ALK1, epithelial markers, melanocytic markers
 - Calretinin-positive and keratin-positive cells may be present.
 - Generally limited in extent
- Molecular and cytogenetic:
 - Cytogenetic abnormalities (e.g., trisomies) on chromosomes 8 and 20 identified:
 - Support neoplastic rather than reactive nature of fibromatosis
 - Germline mutations of APC gene on long arm of chromosome 5:
 - Primarily identified in setting of Gardner-type FAP
 - Mutations in gene encoding β -catenin (*CTNNB1*):
 - Identified in up to 85% of sporadic lesions
 - APC and *CTNNB1* mutations result in intranuclear accumulation of β -catenin.

Differential Diagnosis

- Reactive fibrosis
- Fibrosarcoma:
 - In contrast to fibrosarcoma, fibromatoses lack a herringbone growth pattern, hypercellularity, and increased mitotic rate.
- Peripheral nerve sheath tumor (neurofibroma, benign schwannoma)
- Solitary fibrous tumor
- Myofibromatosis
- Nodular fasciitis:
 - Presence of stellate cytomorphology, loose myxoid stroma, and hemorrhage not features typically seen in fibromatosis
 - Absence of nuclear β -catenin reactivity
- Myofibroblastic tumors (inflammatory myofibroblastic tumor, low-grade myofibroblastic sarcoma)
- Myxoma and fibromyxoma
- Fibro-osseous lesion (fibrous dysplasia, ossifying fibroma)

Treatment and Prognosis

- Preferred treatment is wide surgical excision, including several centimeters beyond the apparent macroscopic extent of the lesion.
- In general, the prognosis is good; however, these lesions present difficulties in management due to insinuation of the lesion into adjacent structures without clear demarcation, making complete excision difficult.
- As a result of the difficulties in completely excising the lesion, recurrent disease is common:
 - Recurrence usually occurs within the first few years following surgery.
 - Local recurrences usually appear within 2 years of surgery, likely correlating to the presence of positive margins.
- Radiotherapy has been used with some success in patients with residual tumor and/or recurrent disease:
 - Because head and neck fibromatosis often occurs in young patients, caution should be exercised in using radiotherapy because of the potential of these patients to develop complications secondary to radiation treatment.
- Imatinib and sorafenib have been used with varying efficacy in the treatment of primary and recurrent disease.
- Other therapies including hormonal therapy, estrogen antagonists, nonsteroidal anti-inflammatory drugs, and low-dose chemotherapy are used with varying results.
- Death due to uncontrolled local disease may occur but is an extraordinary occurrence.
- Spontaneous regression of the lesion may occur but is rare.
- Regression following radiotherapy may take up to 2 to 3 years.
- In extremely rare cases, transformation to an overt malignancy (fibrosarcoma) has been reported to occur and possibly relates to prior radiation therapy.

Nodular Fasciitis (NF) (Fig. 13-4)

Definition: Benign (myo)fibroblastic neoplastic proliferation presenting as a rapidly enlarging lesion that typically occurs in subcutaneous tissue.

Synonyms: Pseudosarcomatous fasciitis; infiltrative fasciitis, pseudosarcomatous fibromatosis

NOTE: The classification of NF as a non-neoplastic lesion or as a neoplasm is the subject of debate, although the identification of *MYH9-USP6* gene fusion as a recurrent event in NF supports its clonal neoplastic nature rather than a reactive, non-neoplastic lesion.

Clinical

- Represents one of the more common soft tissue lesions
- No gender predilection; predominantly occurs in the third to fifth decades of life:
 - Although considered to occur primarily in adults and infrequently affects infants and children, head and neck involvement is common in the latter group and rare in the former group.
- Most commonly occurs in the upper extremities but is seen involving head and neck sites in up to 20% of cases:
 - In the head and neck, the most common site of involvement is the neck, but NF may occur in and around the external ear.
 - Rarely, involves mucosal sites of the oral cavity and sinonasal tract
 - Can also arise within muscle (intramuscular fasciitis), deep fascia (fascial fasciitis), blood vessels (intravascular fasciitis), soft tissues of the scalp or skull (cranial fasciitis), and in areas lacking fascia including mucosal sites of the upper and lower respiratory tract mucosa and esophagus
 - Characteristically arises from the superficial fascia, accounting for its predominant occurrence in subcutaneous areas
- Most common symptom is that of a painless mass noted for its rapid growth occurring over a 1- to 2-week period:
 - Soreness, tenderness, and even pain may be present.
 - On the basis of a rapidly growing soft tissue mass a primary clinical consideration is that of a sarcoma.
- Cause is unknown; however, trauma is considered a possible initiating factor.

Pathology

Gross

- Tends to be solitary and rarely, if ever, is multiple
- Lesions are typically firm, nodular, tan-white, and unencapsulated but well delineated, measuring less than 3 to 4 cm; larger lesions measuring up to 10 cm infrequently occur.
- On cut section the lesion may be smooth or whorled, varying from firm and tan-white to soft and gelatinous or myxoid; cystic areas may be seen.

Histology

- Circumscribed but unencapsulated lesion composed of a proliferation of plump-appearing spindle-shaped cells arranged in short, irregular fascicles and bundles or in a whorled to nodular appearance

Fig. 13-4. Nodular fasciitis.

A, Surgical excision of a roughly rectangular soft tissue mass immediately above and to the right of the tendon identified in the center of the illustration. **B**, Proliferation of fibroblasts arranged in short, irregular fascicles to whorled appearance in a stroma with abundance ground substance creating a loose or “feathery” growth pattern. **C**, Cellular (myofibroblastic) component includes oval to plump to spindle-shaped cells with oval vesicular nuclei, prominent nucleoli, and basophilic appearing fibrillar cytoplasm; mature lymphocytes and extravasated red cells are present. **D**, Increased mitotic activity is a readily identifiable feature, but atypical mitoses are not seen.

- Stroma is rich in mucopolysaccharides, and this abundance of ground substance imparts a loose or “feathery” growth pattern characteristic of nodular fasciitides.
- Cells are oval, plump, or spindle shaped, vary slightly in size and shape, and have pale-staining nuclei with prominent nucleoli:
 - Cellularity varies and may demonstrate hypercellular and hypocellular areas even within the same lesion.
 - Increased mitotic activity is a prominent feature; however, atypical mitoses are not seen.
- Mature lymphocytes and extravasated erythrocytes are commonly seen scattered throughout the lesion.
- Less commonly identified features include the presence of multinucleated (osteoclast-like) giant cells and lipid-laden macrophages in the central portions of the lesion with plasma cells and histiocytes at the periphery of the lesion.
- Non-endothelial-lined slits or clefts are seen throughout the lesion.
- Collagen fibers may be seen but are thin and delicate rather than arranged in thick bundles; with time, fibrosis and microcysts are seen; the latter may coalesce to form large cystic spaces.
- Immunohistochemistry:
 - Immunoreactivity is present for actins (smooth muscle and muscle-specific) and vimentin:
 - CD68 (KP1) reactivity primarily seen in multinucleated giant cells and occasionally in spindle cells
 - Absence of nuclear β -catenin staining
 - Typically, nonreactive for S100 protein, epithelial markers, and ALK1

- Desmin is usually negative but may rarely be positive.
- Calretinin-positive and keratin-positive cells may be present:
 - Generally limited in extent
- Cytogenetic and molecular biology:
 - Consistent *MYH9-USP6* gene fusion

Differential Diagnosis

- Fibrous histiocytoma
 - Fibrous histiocytoma is less well circumscribed than NF but may share many histologic features with NF.
 - Fibrous histiocytoma and NF are closely related, and transitional forms between these entities occasionally occur.
- Myxoma
 - In contrast to NF, myxoma is a paucicellular to hypocellular lesion typically with poor vascularization.
- Fibromatosis
 - Fibromatosis often is an infiltrative lesion involving muscle, tends to be larger than NF, and is composed of spindle-shaped fibroblastic cells in long, sweeping fascicles separated by a collagenized stroma; nuclear β -catenin positive.
 - Mitotic activity may be seen but are less numerous as compared with NF (see later).
- Inflammatory myofibroblastic tumor (IMT):
 - IMTs are usually immunoreactive for ALK1 whereas NF is not.
- Benign peripheral nerve sheath tumors (schwannoma, neurofibroma):
 - In contrast to NF the cellular component includes wavy to buckled-appearing spindle-shaped cells that lack mitotic activity and that are S100 protein positive.
- Most important aspect of the pathologic diagnosis of nodular fasciitis is not to mistake it for a sarcoma:
 - Malignant neoplasms included in the differential diagnosis are malignant fibrous histiocytoma, fibrosarcoma, malignant peripheral nerve sheath tumors.
 - Differentiation from a sarcoma may be based on invasive growth pattern, increased cellularity characterized by the presence of hyperchromatic nuclei with cellular pleomorphism, atypical mitotic figures, and necrosis.
- Rarely, NF may occur in mucosal sites and in these locations the differential diagnosis can be expanded to include epithelial malignancies such as spindle cell squamous carcinoma (SCSC):
 - Similar to sarcomas the presence of cellular pleomorphism, atypical mitotic figures assist in differentiating NF from SCSC.

- Further, although cytokeratin and p63 reactivity in SCSC is variable, NF are nonreactive with cytokeratin and the presence of cytokeratin and/or p63 staining even if limited in extent would differentiate SCSC from NF.

Treatment and Prognosis

- Conservative but complete surgical excision is the preferred treatment.
- Local recurrence may occur in approximately 2% of all cases; usually occurs shortly following surgery; however, this is not necessarily an indication for additional surgery.
- Spontaneous regression may occur.
- Response (resolution) following intralesional corticosteroid injection has been reported.

Nuchal-Type Fibroma (NTF) (Fig. 13-5)

Definition: Benign fibroblastic proliferation involving dermis and subcutis.

Synonym: Extranuchal or nuchal-like fibroma

Clinical

- Rare lesion
- More common in men than women; occurs over a wide age range including first to eighth decades of life with a peak incidence in the third to fifth decades of life
- Predilects to the subcutaneous tissue of the posterior neck (i.e., nucha); extranuchal sites of involvement may include the upper back (interscapular and paraspinal regions), shoulder, face, extremities, and buttocks:
 - Owing to identical histologic findings shared by nuchal and extranuchal fibromas, the designation nuchal-type fibroma was proposed to encompass all histologically similar lesions.
- Presents as a painful subcutaneous mass; usually solitary but may be multifocal:
 - Notably associated with diabetes mellitus (30% to 40% of patients)
- Early reports documented apparent association of NTF with Gardner syndrome:
 - Such fibromas represent Gardner-associated fibromas rather than NTF.
 - Sufficient differences exist in the clinical and pathologic features between Gardner-associated fibroma and NTF to allow for their distinction.

Pathology

Gross

- Poorly circumscribed, firm to hard, gray to white mass attaining sizes larger than 3 cm

Fig. 13-5. Nuchal fibroma.

A, Acellular lesion composed of dense collagen with vaguely lobular appearance, entrapped cutaneous adnexa, and absent inflammatory cells. **B**, Entrapment of small nerves can be identified.

Histology

- Unencapsulated, acellular, or paucicellular lesion composed of dense collagen, haphazardly arranged collagen fibers forming a vaguely lobular appearance
- Entrapment and/or encasement of cutaneous adnexa, adipocytes, and small nerves may be identified.
- Expansion into subjacent skeletal muscle may be identified.
- Inflammatory cells are absent to sparse.

Differential Diagnosis

- Scar
- Lipoma and fibrolipoma

- Elastofibroma:
 - Deep-seated lesions of connective tissues typically located between the lower portion of the scapula and the chest wall:
 - Rare examples occur in lower extremity.
 - Peak incidence in the seventh and eighth decades of life; marked predilection for females
 - Slowly growing, poorly defined mass attached to periosteum of the ribs
 - Believed to develop from long-standing repeated trauma to tissues between scapulae and chest wall:
 - Clustering of cases (in particular in Japan) suggests genetic predisposition.
 - Cytogenetic and molecular analyses have shown clonality, further supporting genetic predisposition.
 - Irregular bands of dense hypocellular to paucicellular collagenous fibrous tissue and abundant eosinophilic elastic fibers; entrapped mature fat is present.
 - Elastic stain highlights beaded and lobular elastic fibers.
 - Scattered spindle cells are negative for smooth muscle actin, desmin, and S100 protein.
 - Surgical excision is preferred treatment.
 - No tendency for local recurrence
- Gardner-associated fibroma (GAF):
 - Usually occurs in younger patients than NTF:
 - Majority present in first decade of life
 - Mean age of 5 years reported
 - Most common locations include the back and paraspinal region.
 - Histologically composed of densely collagenized tissue with sparse population of bland spindle-shaped cells interspersed with lobules of mature adipose tissue
 - Entrapment of nerves, blood vessels, and fat at the periphery of the lesion can be identified but increased numbers of small nerve bundles as seen in NTF are not present in GAF.
 - Immunoreactivity for CD34, CD99, and β -catenin
 - May recur following incomplete excision
 - May be associated with desmoids (synchronous, metachronous)
 - Association with FAP; development of fibroma may precede years prior to manifestations/diagnosis of the syndrome
- Fibromatosis

Treatment and Prognosis

- Simple excision is the preferred treatment but NTF often recurs.
- No metastatic potential

LYMPHATIC MALFORMATIONS (TUMORS OF LYMPHATIC VESSELS)

General Considerations

- Believed to represent developmental malformation rather than true neoplasm; hence the current designation as lymphatic malformations
- Subclassified according to size, including:
 - Microcystic
 - Macrocystic (cysts greater than 0.5 cm)
 - Combined
- Diffuse lymphatic malformations involving multiple organs referred to as lymphangiomatosis
- Much less common than hemangiomas
- Majority are benign
- Differences between vascular and lymphatic endothelium can be achieved by immunohistochemical staining:
 - Lymphatic endothelium:
 - PROX1, LYVE1, VEGFR3 D2-40 (podoplanin) and CD31 positive
 - CD34 negative to weakly positive
 - Absence of type IV collagen and laminin around lymphatic endothelium correlates ultrastructurally to absence of basement membrane or pericytes investing lymphatic endothelial cell
 - Vascular endothelium:
 - CD34, CD31, and D2-40 positive
 - PROX1, LYVE1, VEGFR3 negative
 - Presence of type IV collagen and laminin around vascular endothelium correlates ultrastructurally to presence of basement membrane or pericytes investing vascular endothelial cell
- Classification of lymphangiomas includes:
 - Cavernous lymphangioma
 - Cystic hygroma
 - Lymphangioma circumscriptum
 - Acquired progressive lymphangioma (benign lymphangioendothelioma)
 - Lymphangiomatosis (diffuse lymphatic malformation involving multiple organs)
 - Multifocal lymphangiomatosis and thrombocytopenia
- May be further subclassified by size, including:
 - Microcystic
 - Macrocystic (cysts greater than 0.5 cm)
 - Combined
- In the head and neck, the most common type of lymphatic malformation (lymphangioma) is cystic hygroma.

Lymphatic Malformation (Cystic Hygroma) (Figs. 13-6 through 13-8)

Definition: Benign lesion of lymphatic spaces.

- Name derived from Greek: fluid (*hygros*) tumor (*oma*)
- Appears to be a variant of cavernous lymphangioma

Clinical

- No gender predilection; usually present at birth:
 - Up to two thirds of cases diagnosed at birth
 - From 80% to 90% identified by 2 years of age
 - Rarely occurs in adults
- May occur anywhere in the body but most commonly are seen in the head and neck region
- In the head and neck, majority are identified in the lateral neck (posterior and anterior triangles)
 - Rarely seen in the midline
 - May extend into the thorax
- Presentation is usually as a painless, soft neck mass, which can achieve large sizes, filling the entire side of the neck:
 - Large lesions compress adjacent structures, potentially causing dysphagia, dyspnea, and stridor.
 - Pain is not commonly seen unless infection is present.
- Presumed to arise as congenital anomalies of the jugular lymphatic sac.
- Due to the potential for extension of the lesion away from the neck (e.g., intrathoracic), appropriate clinical evaluation should include complete radiographic evaluation including chest radiographs.
- Radiology:
 - Well-circumscribed, fluid-filled, solitary, or multicystic mass varying in density based on the presence or absence of intracystic hemorrhage or infection
- Congenital or acquired:
 - Commonly seen in patients with Turner syndrome
 - Can be associated with other congenital anomalies, including:
 - Thyroglossal duct cysts, harelip, congenital heart anomalies, hand and feet deformities, Down syndrome
 - Associated with raised amniotic fluid levels of alpha-fetoprotein, which may be seen in cases of in utero cystic hygromas

Pathology

Gross

- Soft, single or multiloculated, compressible mass varying in size from a few centimeters to greater than 30 cm

Fig. 13-6. Cystic hygroma.

A through **D**, Lateral neck masses in different aged patients, including one (**D**) that occurred in utero.

Fig. 13-7. Cystic hygroma.

Axial CT scan of this 3-year-old child shows multiple cystic masses in the right supraclavicular fossa and the lower posterior triangle of the neck. This is a typical appearance of cystic hygromas (cystic lymphangiomas). (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 2267, Fig. 37-48, A.)

- Overlying skin may appear unremarkable or atrophic and may have a blue hue.
- In cases uncomplicated by hemorrhage or infection, the cysts contain clear to lightly pink watery fluid.

Histology

- Large, irregularly shaped spaces lined by a single layer of endothelial cells and containing proteinaceous fluid and lymphocytes
- Intervening stroma contains small amounts of fibrous connective tissue and muscle with lymphoid aggregates; however, the stroma may become inflamed and fibrotic following repeated infections.
- Immunohistochemistry:
 - Podoplanin (D2-40) reactivity
 - PROX1 and VEGFR3 positive:
 - Greater sensitivity than podoplanin
 - CD31 positive and CD34 absent but may be variably reactive
 - Glucose transporter protein 1 (GLUT1) negative

Differential Diagnosis

- Branchial cleft cyst
- Thyroglossal duct cyst
- Teratoma
- Ranula

Fig. 13-8. Cystic hygroma.

A and B, The histology of lymphatic malformation (cystic hygroma) is characterized by large, irregularly shaped spaces lined by a single layer of endothelial cells and containing proteinaceous fluid and lymphocytes. **C,** The intervening stroma may contain lymphoid aggregates as seen in the center of this image. Other mesenchymal structures that may be present include small amounts of fibrous connective tissue, smooth muscle, and adipose tissue. The latter is present in part **A** at the extreme right of that illustration.

Treatment and Prognosis

- Some lymphangiomas may undergo spontaneous regression and in infants with uncomplicated lesions, surgery should be postponed until 3 to 5 years of age to allow for regression of the lesion:
 - If no sign of involution by age 5, then surgery is indicated.
 - Complete excision is recommended.
 - Recurrent infections and symptoms of compression or life-threatening symptoms necessitate surgical intervention at younger ages.
 - Other therapeutic modalities that have been used with varying success include radiation, intralesional injection of corticosteroids, sclerosing agents, and cryosurgery.
 - Advances in sclerotherapy with OK-432 (picibanil), a lyophilized mixture with group A *Streptococcus pyogenes*, have shown significant promise:
 - Approximately one third of cases respond to sclerotherapy with OK-432.
 - Initial and long-term response rates are equally good and reported to be 84% and 76%, respectively.
 - Safe, effective, and associated with few side effects
 - Factors predicting good response include:
 - Location in head and neck
 - Size less than 5 cm
 - Macrocystic architecture
- Recurrence rates following surgery range from 5% to 10% and may represent persistence rather than true recurrence of the lesion.
- No malignant potential
- Lesions may extend extensively through soft tissue structures and can extend to the base of skull, floor of mouth, and into the mediastinum and/or thoracic cavity.
- Death due to pneumonia, airway obstruction, or atelectasis may rarely occur.

NEUROENDOCRINE NEOPLASMS

Paragangliomas

Definition: Benign neuroendocrine tumor arising from the neural crest–derived paraganglia of the autonomic nervous system.

General Considerations

- Paragangliomas can be divided into adrenal and extra-adrenal.
- Adrenal-derived paraganglioma arising from the adrenal medullary chromaffin cells is traditionally referred to as a pheochromocytoma.
- Extra-adrenal paraganglia are divided into sympathetic and parasympathetic types:
 - Differences include anatomic distribution and secretory product:
 - Sympathetic paraganglia:
 - Axial region of the trunk along prevertebral and paravertebral sympathetic chains and in connective tissue in and around pelvic organs
 - Produce catecholamines
 - Tumors associated with sympathetic system produce epinephrine (adrenaline)
 - Tumors associated with clinical symptomatology related to excess catecholamine production are usually of the sympathetic paraganglia.
 - Less likely to be familial
 - More likely to be malignant
 - Parasympathetic paraganglia:
 - Localized to head and neck along branches of the glossopharyngeal nerve (jugulotympanic paraganglioma) and vagus nerve (carotid body paraganglioma)
 - Produce catecholamines:
 - Secretory product tends to be dopamine
 - Not usually associated with clinical symptoms due to secretory product
 - Greater tendency to occur in patients with hypoxemia
 - More often familial
 - Less likely to be malignant
- Terminology/classification of extra-adrenal paraganglia includes paraganglioma prefaced by the anatomic site of occurrence:
 - Paragangliomas of the head and neck include:
 - Carotid body paraganglioma
 - Jugulotympanic paraganglioma (middle ear and temporal bone)
 - Vagal paraganglioma
 - Rare head and neck sites of occurrence include:
 - Laryngeal paraganglioma
 - Primary thyroid paraganglioma
 - Paraganglioma of the nasal cavity and nasopharynx
 - Most common site of occurrence in the head and neck is the carotid body; jugulotympanic paragangliomas represent the second most common site of occurrence (see Section 7, Ear).

Carotid Body Paraganglioma (Figs. 13-9 through 13-11)

Definition: Benign neuroendocrine tumor arising from the carotid body paraganglia with characteristic histologic findings:

- Carotid body paraganglia are paired, bilateral aggregates of neuroendocrine tissues identified in the

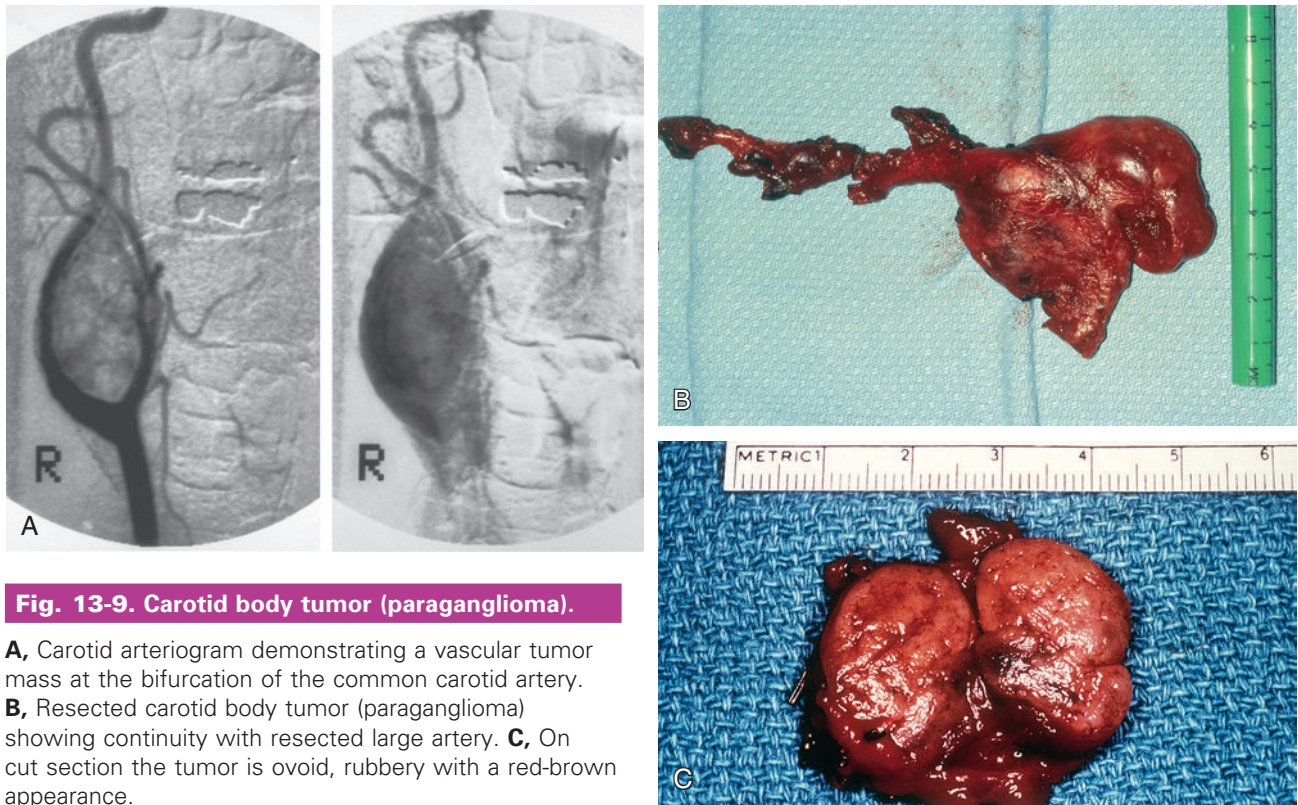

Fig. 13-9. Carotid body tumor (paraganglioma).

A, Carotid arteriogram demonstrating a vascular tumor mass at the bifurcation of the common carotid artery.

B, Resected carotid body tumor (paraganglioma) showing continuity with resected large artery. **C,** On cut section the tumor is ovoid, rubbery with a red-brown appearance.

medial aspect of the common carotid artery and its bifurcation:

- Along with the aortic body paraganglia function as chemoreceptors
- Sensitive to changes in oxygen tension, carbon dioxide content, and hydrogen ion concentration

Synonyms: Chemodectoma; carotid body tumor; glomus tumor; nonchromaffin paraganglioma

Clinical

- Uncommon tumor but considered to be the most common paraganglioma in the head and neck
- No gender predilection in tumors occurring at sea level; significant female predilection in tumors occurring at higher altitudes:
 - Female predilection at higher altitudes hypothesized to be related to monthly menstrual loss of blood and larger pulmonary capacity with resulting (chronic) hypoxia.
- Occurs over a wide age range but is most common in the fifth to sixth decades of life; uncommon in children
- Most common symptom is a painless, slowly enlarging neck mass typically localized deep to the anterior border of the sternocleidomastoid muscle just below the angle of the mandible:
 - Often, the mass has been present for years prior to the patient seeking medical attention
 - Frequently a palpable (anterolateral) neck mass
- Typically vertically fixed and laterally mobile due to its fixation to the carotid artery
- May be pulsatile; bruits reported in 10% to 16% of cases
- May become adherent or invasive as they enlarge:
 - May encase carotid arteries (external and/or internal)
 - May extend to parapharyngeal space, causing submucosal bulging in the lateral oropharynx
- Typically unilateral but may infrequently be bilateral and/or multifocal:
 - Other paragangliomas seen may include vagal paraganglioma and jugulotympanic paraganglioma
 - May be combined in association with a pheochromocytoma
 - May occur in association with thyroid carcinoma
 - May be a component of multiple endocrine neoplasia (MEN) syndrome or Carney's triad
- In general, this is a slow-growing tumor but it can attain a large size, leading to additional symptoms including:
 - Parapharyngeal or hypopharyngeal mass
 - Hoarseness
 - Cranial nerve deficits (10% to 30%), pain (25%), vocal cord paralysis, dysphagia, and Horner syndrome
 - Horner syndrome results from an interruption of the sympathetic nerve supply to the eye and

Fig. 13-10. Carotid body tumor (paraganglioma).

A, Characteristic histologic picture includes a cell nest or “Zellballen” growth pattern with a prominent fibrovascular connective tissue stroma surrounding and separating the nests. **B**, The neoplasm is composed predominantly of chief cells, which are round or oval with uniform nuclei, dispersed chromatin pattern, and abundant eosinophilic, granular, or vacuolated cytoplasm peripherally surrounded by sustentacular cells, which are often difficult to identify by light microscopy and appear as spindle-shaped, basophilic cells. **C**, Chief cells are diffusely immunoreactive with synaptophysin. **D**, Characteristic S100 protein staining is identified in peripherally situated sustentacular cells. **E**, Sox10 is another marker showing reactivity in the sustentacular cells in paragangliomas.

Fig. 13-10, cont'd

F, Intravascular foreign material (*arrows*) is evidence of preoperative embolization. Note the absence in the tumor of characteristic organoid or cell nest pattern of growth typically seen in paragangliomas. **G**, In addition to absence of organoid pattern of growth there is associated dense fibrous stroma, suggesting infiltrative growth that may result in erroneous interpretation, including a malignant neoplasm; note the intravascular embolization material (*arrow*).

- is characterized by the classic triad of miosis (i.e., constricted pupil), partial ptosis, and loss of hemifacial sweating (i.e., anhidrosis)
- Headache and syncope
- Rarely, may be functional but, in general, is nonfunctional, which is true relative to other paragangliomas of the head and neck
- Increased incidence of carotid body hypertrophy and carotid body paragangliomas in populations living in high altitudes likely related to chronic hypoxemia:
 - Ninefold increase in carotid body paragangliomas in people living between 2000 and 3000 m above sea level and 12-fold increase in incidence in people living between 3000 and 4500 m above sea level
 - In addition, carotid body tumors occurring in patients at higher altitudes as compared with those occurring in patients at sea level:
 - Predilect to women
 - Lower rate of bilaterality
 - Less frequent familial history
 - A higher incidence of carotid body hypertrophy and carotid body paragangliomas in patients with chronic obstructive pulmonary disease likely related to chronically low pO_2 levels.
- Radiology
 - Carotid arteriogram:
 - Hypervascular tumor mass at the bifurcation of the common carotid artery that may (eventually) result in splaying of the internal and external carotid arteries
 - Tumor may extend superiorly and involve the parapharyngeal space.
 - Contrast-enhanced CT:
 - Homogeneous, hypervascular, well-delineated soft tissue mass
 - MRI with gadolinium:
 - T1-weighted:
 - Well-defined hypointense mass with areas of signal void
 - T2-weighted:
 - Due to areas of high vascularity associated with hemorrhage or slow blood transfusion, a “salt and pepper” pattern is identified.
 - May allow for detection of smaller lesion
 - Octreotide scintigraphy:
 - As a neuroendocrine tumor, paragangliomas have a high density of somatostatin 2 receptors on their cell surface.
 - Octreotide is a somatostatin analog; when coupled with radioisotope indium III, octreotide creates a scintigraphic image of tumors expressing somatostatin type 2 receptors.
 - Noninvasive imaging modality used to confirm diagnosis:
 - Diagnostic accuracy of 90%, sensitivity of 94%, and specificity of 75% in tumor detection
 - Used to detect additional small and/or occult tumors
 - Used to screen patients at risk for familial (inherited) paraganglioma(s)

Fig. 13-11. Malignant paraganglioma.

Features that may be associated with malignancy but that are not definitive for malignancy include **(A and B)** increased mitotic activity and necrosis, the latter usually seen within the center of the cell nests. **(C)** Perineural and intraneural invasion (*arrows*) may be seen in paragangliomas but is not considered evidence of malignancy. **(D)** Synaptophysin strongly details the paraganglioma (*arrows*) lying adjacent to and within a peripheral nerve, the latter with less intense but positive synaptophysin staining. **E and F**, Definitive evidence for malignancy in a paraganglioma is predicated on the presence of metastatic disease as seen in these illustrations showing the tumor within the subcapsular sinus of a cervical neck lymph node diagnostic for metastatic paraganglioma.

- Cause includes chronic hypoxia and familial inheritance (hereditary paraganglioma)
- May develop in association with various hereditary disorders, including:
 - MEN type 2A
 - MEN type 2B
 - von Hippel-Lindau syndrome
 - Neurofibromatosis type 1 (NF1)
- Familial or hereditary paraganglioma:
 - Overall 10% to 50% of paragangliomas are familial
 - Autosomal-dominant inheritance with genomic imprinting:
 - Paternal transmission of the gene
 - No tumor when gene inherited from the mother
 - One third of familial carotid body paragangliomas are bilateral, which may be synchronous or asynchronous.
 - Hereditary deficiency of clotting factors VII and X identified in few patients with familial carotid body paraganglioma
 - Genetic analysis in hereditary paragangliomas have shown three loci associated with these tumors:
 - Paraganglioma 1 (PGL1) on chromosome 11q23
 - Paraganglioma 2 (PGL2) on chromosome 11q13.1
 - Paraganglioma 3 (PGL3) on chromosome 1q21-q23
 - Genetic testing may assist in early diagnosis and/or identification of patients at risk for familial (hereditary) paraganglioma.
 - Germline mutations in succinate dehydrogenase (SDH) genes implicated in the pathogenesis of hereditary paraganglioma:
 - SDH is a mitochondrial enzyme complex with important role in oxidative phosphorylation and intracellular oxygen sensing and signaling
 - Mutations in three genes (*SDHB*, *SDHC*, and *SDHD*) implicated in the pathogenesis of hereditary paraganglioma
 - These genes appear to function as tumor suppressor genes.
 - Genes participate in encoding distinct subunits of a hetero-oligomeric electron transport chain in the Krebs cycle.
 - Identification of the causative genes allows for detection of individuals at risk for these tumors.
 - Paraganglioma (PGL) syndrome includes inherited head and neck paragangliomas and adrenal or extra-adrenal pheochromocytomas and are classified according to the susceptibility genes *SDHB*, *SDHC*, and *SDHD*.
- Germline mutations of genes encoding *SDHB* and *SDHC* predispose to paraganglioma syndromes:
 - *SDHD* gene identified as the susceptibility gene for PGL type 1 (PGL1)
 - *SDHB* gene identified as the susceptibility gene for PGL type 4 (PGL4)
 - Very few PGL type 3 (PGL3) families have been identified with a germline mutation of *SDHC* gene.
 - Susceptibility gene for PGL type 2 (PGL2) remains unidentified.
 - Head and neck paragangliomas associated with *SDHC* mutations are virtually exclusively benign and seldom multifocal.
 - *SDHD* mutation carriers (PGL1) have more frequent multifocal paragangliomas and are rare in patients with sporadic single tumors.
 - *SDHB* mutation carriers (PGL4) are more likely to develop malignant disease and possibly extraparaganglial neoplasias, including renal cell carcinoma and thyroid carcinomas
- If a diagnosis of carotid body paraganglioma is clinically suspected, then open biopsy is contraindicated due to risk of hemorrhage.
- Grouping of carotid body tumors according to size and vessel involvement is inconsistent in the literature; classification of carotid body paragangliomas (Shamblin's surgical classification) is based on surgical findings related to carotid artery involvement (Table 13-3).

Pathology

Gross

- Encapsulated or well-circumscribed, ovoid, rubbery to firm, red-pink to tan-gray tumor of varying size from 2 to 6 cm in greatest dimension
- A centrally or peripheral placed identifiable large artery may be identified associated with the tumor mass.

TABLE 13-3 Shamblin's Surgical Classification of Carotid Body Tumors

Group I	Tumors are relatively small with minimal attachment to carotid vessels
Group II	Tumors are larger with moderate arterial attachment and can be resected with precise surgical dissection
Group III	Larger tumors encasing the carotid arteries and can be resected only with arterial sacrifice

Histology

NOTE: Regardless of the site of origin, the histologic appearance of all extra-adrenal paragangliomas is the same.

- Characteristic cell nest, organoid, or “Zellballen” pattern of growth with tumor nests surrounded and separated by fibrovascular stroma
- Neoplasm is composed predominantly of chief cells and peripherally situated sustentacular cells:
 - Chief cells (so-called type I cells):
 - Round or oval with uniform nuclei, dispersed chromatin pattern and abundant eosinophilic, granular, or vacuolated cytoplasm
 - Sustentacular cells (so-called type II or supporting cells):
 - Represent modified Schwann cells
 - Identified at the periphery of the cell nests as spindle-shaped, basophilic-appearing cells
 - May be difficult to identify by light microscopy
- No glandular or alveolar differentiation seen
- Cellular pleomorphism may be present; mitoses and necrosis are infrequently identified:
 - Necrosis may be identified in those tumors successfully embolized prior to surgery.
- Spindling of the chief cells may be seen and infrequently may predominate.
- Preoperative embolization:
 - Very useful adjunct to surgery of large paragangliomas
 - Used in the attempt to shrink the size of the tumor as well as reducing intraoperative bleeding is generally associated with easier dissection (e.g., more obvious tissue planes, less risk to normal anatomic structures)
 - Risks include escape of embolizing particles into cerebral circulation with risk of stroke
 - May result in the identification of intravascular and extravascular foreign material (with or without associated multinucleated giant cells) in resection specimens
- Similar to jugulotympanic paragangliomas (see Section 7), carotid body paragangliomas, and other paragangliomas may not display characteristic cell nest or organoid growth but appear compressed due to artifactual distortion secondary to surgical manipulation (“squeezing”) of the tissue during removal:
 - In addition to the loss of an organoid pattern of growth, carotid body paragangliomas may be associated with a dense fibrous stroma and an appearance of infiltrative growth.
 - These findings may result in overlooking a diagnosis and thus in an erroneous interpretation including a malignant neoplasm.
- Awareness of this occurrence and use of appropriate special stains should allow for a correct diagnosis.
- Infiltrative growth including perineural invasion and/or lymph-vascular invasion may be identified but is not indicative of malignancy and/or considered to have prognostic import (see later for criteria of malignancy).
- Histochemistry:
 - Tumor cells are argyrophilic positive.
 - Reticulin staining delineates the cell nests.
 - Argentaffin, mucin, and periodic acid Schiff stains are negative.
- Immunohistochemistry:
 - Chief cells:
 - Chromogranin, synaptophysin, CD56, neuron-specific enolase and GATA3 (nuclear) positive
 - Calcitonin negative
 - Cytokeratins, carcinoembryonic antigen, and other epithelial markers negative (rarely, cyto-keratin staining reported)
 - CD10 negative
 - Myogenic markers and melanocytic markers (HMB45, melan-A, tyrosinase, MITF1) negative
 - Sustentacular cells:
 - S100 protein and glial fibrillary acidic protein positive
 - Sox10, a transcription factor in neural crest developed and differentiation of neural crest cells into melanocytic and schwannian lineage, may also be reactive (nuclear staining) in the sustentacular cells of paragangliomas (and pheochromocytoma)
- Electron microscopic:
 - Hallmark of the EM findings is the presence of neurosecretory granules.

Differential Diagnosis

- Rhabdomyoma
- Hemangiopericytoma
- Neuroendocrine carcinoma
- Alveolar soft part sarcoma
- Metastatic medullary carcinoma of the thyroid gland
- Metastatic renal cell carcinoma

Treatment and Prognosis

- Surgical excision is the preferred treatment, which may necessitate excision of one or more branches of the carotid arterial system:
 - Relative contraindications to surgery include:
 - Extensive skull base or cranial involvement
 - Advanced patient age
 - Medical comorbidities

- Bilateral or multifocal tumors that may result in unacceptable postoperative morbidity with resultant bilateral lower cranial nerve palsies
- If surgery is the chosen treatment course, then preoperative embolization is performed:
 - Embolization is a useful adjunct in treatment, especially of large paragangliomas
 - Main objective of embolization is directing the embolism material to selectively permeate only the vascularity of the paraganglioma without proximal occlusion of the feeding artery
 - Postembolization arteriography is performed to document the absence of tumor “blush” with continued patency of the external carotid system
 - Successful embolization results in improved surgical resection directly related to decreased tumor vascularity with reduction in tumor size as much as 25% due to diminished tumoral blood flow
 - Reduction of tumor size results in less manipulation of surrounding structures required for exposure during surgery.
 - In addition, embolization results in less blood loss during surgical dissection of the tumor.
 - Essential that surgery be performed within 48 hours of embolization to avoid recruitment of collateral circulation
- Radiotherapy initially used to treat unresectable tumors (i.e., extensive skull base involvement or intracranial extension) or for surgical treatment failures has become an established treatment modality in untreated lesions and has been incorporated into the treatment algorithms for head and neck paragangliomas:
 - External beam radiation, intensity modulated radiation therapy, and stereotactic radiation therapy have been used with excellent results.
 - Most commonly treated site has been jugulotympanic paraganglioma > carotid body or vagal paraganglioma.
 - Conventional fractionated radiotherapy and stereotactic radiosurgery have been used:
 - Stereotactic radiosurgery (SRS) offers the possibility of a single, highly focused small-field treatment with a steep dose gradient to maximally spare surrounding normal tissue.
 - SRS delivered by either radioactive cobalt sources (gamma knife) or generation of radiation from a linear accelerator (LINAC)
 - Successful treatment with radiotherapy defined as local control with stability or regression of tumor size and nonprogression or improvement in neurologic symptoms
 - Rarely, total resolution of the tumor occurs following radiotherapy.
- Prognosis is excellent following complete resection:
 - Recurrence may occur in up to 10% of patients and generally is correlated to inadequate surgical excision.
- Benign tumors with indolent biology; however, some tumors may be locally invasive (and not malignant)
- Approximately 10% may be malignant as manifested by local invasion or metastases to regional lymph nodes or to the lung.
- Malignant paragangliomas:
 - Sporadic (nonfamilial) tumors are more likely to be malignant than familial or inherited paragangliomas.
 - SDHB mutation carriers (PGL4) are more likely to develop malignant disease and possibly extraparaganglial neoplasias including renal cell carcinoma and thyroid carcinomas.
 - Incidence of malignancy in carotid body paragangliomas is from 2% to 13% of cases.
 - Morphologic features correlating with malignant behavior not well defined and histology is not predictive of behavior:
 - Local invasion considered poor predictor of metastasis; absence of invasion does not preclude development of metastatic disease.
 - Histologic criteria for malignancy:
 - Unequivocal evidence:
 - Metastatic tumor to lymph nodes or viscera (e.g., lung, liver, bone)
 - Features that may be associated with malignancy but that are not definitive for malignancy include:
 - Increased mitotic activity
 - Necrosis usually seen within the center of the cell nests
 - Lymph-vascular invasion
 - Perineural invasion
 - DNA ploidy
 - Absence of sustentacular cells
 - Histologic criteria for malignancy can also be identified in benign paragangliomas; therefore metastasis is considered to represent the only true criterion for malignant paraganglioma.
 - Estimated 10% malignancy rate associated with carotid body paragangliomas may be high and may represent multicentric occurring paragangliomas.
 - Treatment for malignant paragangliomas includes resection of the primary and metastatic lesions with postoperative radiotherapy.
 - Limited literature relative to follow-up/prognosis of malignant carotid body paragangliomas but include disease-free survival from 15 months to 6 years

BENIGN NEOPLASMS OF ADIPOSE TISSUE

General Considerations

- Adipose tissue is divided into two types:
 - White fat:
 - Contains a high percentage of lipids (80% to 90%) with a greater concentration of triglycerides
 - Ultrastructurally, contains few mitochondria lying with little direct contact with fat vacuoles
 - With age, amount of white fat increases
 - Most lesions/tumors of adipose tissue are of white fat
 - Tumors of white fat collectively referred to as lipomas
 - Brown fat:
 - Contains lower percentage of lipids (40% to 50%) with a greater percentage of phospholipids
 - Ultrastructurally, contains numerous pleomorphic mitochondria lying in intimate contact with fat vacuoles
 - With age, amount of brown fat decreases
 - Tumors of brown fat referred to as hibernoma
- Adipocytic tumors represent one of the largest single groups of soft tissue tumors:
 - Primarily due to high incidence of benign subcutaneous lipomas
- Other than lipomas and hibernoma, other lesions/tumors of fat include:
 - Fat necrosis
 - Lipoblastoma and lipoblastomatosis
 - Benign symmetric lipomatosis

Lipomas

Definition: Benign tumor of mature (white) adipose tissue.

Clinical

- Overall, lipomas represent the most common mesenchymal tumor in adults:
 - Primarily due to high incidence of benign subcutaneous lipomas
- Lipomas of childhood are uncommon.
- Approximately 15% of all lipomas occur in the head and neck region.
- Lipomas can be seen in all areas of the head and neck, but the most common site of occurrence is the neck area, especially the posterior neck:
 - Other sites in which lipomas are seen include parotid gland, oral cavity (buccal mucosa), pha-

ryngeal region (hypopharynx and retropharynx), and larynx (see Section 5 for discussion on laryngeal lipomas)

- Intraoral lipomas:
 - Most common site is the buccal mucosa followed by the tongue, lips, and floor of mouth.
- More common in men than women; occur in all age groups but most commonly seen in the fifth and sixth decades of life
- Symptoms are generally related to a painless soft tissue mass; exceptions include:
 - Pain and/or sensory and motor nerve disturbances are rarely seen but may occur by compression of nerves by large tumors
 - Upper respiratory tract lipomas present with symptoms related to airway obstruction, problems with deglutition, or voice disturbances (hoarseness, voice changes); often, symptoms manifest only after the tumor has reached a considerably large size.
- Usually solitary but may be multiple
- Radiology:
 - Homogeneous soft tissue mass isodense to the subcutaneous tissue

Pathology

Gross

- Well-circumscribed to encapsulated, soft and round, and varying in size from a few millimeters to greater than 20 cm
- Cut section shows an irregular lobular pattern with a yellow color and a soft, greasy consistency.

Histology

- Classification of lipomas based on histologic findings, as well as other parameters (e.g., clinical) and include:
 - Conventional or ordinary lipoma
 - Angiolipoma
 - Relatively unique clinical and histopathologic findings to merit specific categorization except not common in the head and neck region
 - Angiomyolipoma:
 - Belong to family of perivascular epithelioid cell tumor (PEComa), see later
 - Myxoid lipoma
 - Fibrolipoma
 - Angiomyolipoma
 - Myolipoma
 - Myelolipoma
 - Chondroid lipoma
 - Intramuscular (infiltrating) lipoma
 - Pleomorphic lipoma and spindle cell lipoma:
 - Relatively unique clinical and histopathologic features, including common occurrence in the neck region and cytogenetic findings,

Fig. 13-12. Cervical neck lipoma.

A, The tumor is encapsulated, irregularly shaped, yellow, and focally attached to the submandibular gland (*lower left*). **B**, Characteristic histologic appearance of a lipoma composed of uniform-appearing mature fat cells (adipocytes) with little variation in size and shape. **C**, At higher magnification the adipocytes consist of vacuolated cells with compression and peripheral placement of the nuclei.

respectively, to merit more specific categorization rather than simply representing a histologic type/variant of lipoma (see later)

Conventional Lipoma (Fig. 13-12)

- Thin capsule surrounding a tumor arranged in a lobular growth pattern
- Tumor is composed of mature fat cells (adipocytes) consisting of a vacuolated cell with compression and peripheral placement of the nucleus; little variation in size and shape of the adipocytes.
- Lipoblasts are not seen.
- Richly vascularized but typically the vascular network is difficult to identify due to compression by distended lipocytes
- Secondary changes due to trauma or vascular compromise include necrosis, hemorrhage, infarction, calcification, and cyst formation.
- Cytogenetics and molecular genetics:
 - Chromosome aberrations found in 55% to 75% of cases with three cytogenetically defined subgroups:
 - Translocations involving 12q13-15 (65%)
 - Rearrangements of 13q (10%):
 - Deletions and structural rearrangements of the long arm of chromosome 13 are frequently observed in benign (and low-malignant) lipomatous tumors.
 - Rearrangements of 6p21-23 (5%)
 - Rearrangements of *HMGIC* gene (also referred to as *HMG2* gene) found
 - Some have gains of *MDM2*.
- Histologic types of lipomas include:
 - Myxoid lipoma:
 - Presence of mucoid or myxoid stroma replacing portions of the tumor
 - Fibrolipoma and sclerotic lipoma:
 - Fibrolipoma: admixture of fibrous connective tissue (not associated with the capsule or fibrous septa), which may be hyalinized
 - Sclerotic lipoma: predominance of sclerotic fibrous tissue with only focal lipocytic areas:
 - Predilection for sclerotic lipoma to occur on the scalp or hands of young men

Fig. 13-13. Angiolipoma.

A, Angiolipoma is characterized by the presence of mature adipose tissue separated by branching network of small blood vessels. **B**, Intravascular fibrin thrombi are seen at higher magnification.

○ Angiolipoma (Fig. 13-13):

- Primarily is a subcutaneous nodule localized to the forearm in young adults
 - Other sites of occurrence include the trunk and upper arm.
- Striking male predominance; most common in early adulthood
- Characteristically are painful.
- Multiple angiolipomas are more common than solitary angiolipomas.

- Histologically, characterized by:
 - Presence of mature adipose tissue proliferation separated by branching network of small blood vessels
 - Fibrin thrombi identified within vascular component, a feature not seen in conventional lipoma
 - Prominent mast cell component
- Cellular angiolipoma represents a histologic subtype, in which the tumor is hypercellular and predominantly composed of vascular channels.
- May be familial
- Trauma implicated as potential contributing or initiating factor
- Angiomyolipoma (AML) (Fig. 13-14):
 - Specific lesion usually localized to one or both kidneys
 - Belongs to family of perivascular epithelioid cell tumor (PEComa):
 - PEComas are mesenchymal tumors composed of distinctive cells that show focal association with blood vessel walls and usually express melanocytic and smooth muscle markers
 - PEComa family includes:
 - Angiomyolipoma (AML)
 - Clear cell “sugar” tumor of the lung
 - Lymphangioleiomyomatosis (LAM)
 - Lesions known as malignant epithelioid angiomyolipoma of the kidney that may also occur in the retroperitoneum and are better termed malignant PEComa.
 - Less common extrarenal sites of occurrence include liver, heart, lung, colon, skin, nasal cavity, and oral cavity.
 - More common in women than men
 - Associated with abdominal or flank pain, hematuria, or chills and fever
 - Associated lesions may include:
 - Tuberous sclerosis complex occurring in approximately 50% of cases
 - Renal cell carcinoma
 - Neurofibromatosis
 - Pulmonary lymphangiomyoma and lymphangiomyomatosis
 - Angiomyolipomas are histologically characterized by the presence of three tissue components:
 - Mature adipose tissue
 - Thick-walled blood vessels often with hyalinization of the media and minimal to abnormal elastica
 - Bundles of smooth muscle often with prominent perivascular localization:

Fig. 13-14. Angiomyolipoma.

A, Angiomyolipoma is characterized by the presence of mature adipose, thick-walled blood vessels surrounded by smooth muscle. **B**, At higher magnification the smooth muscle cells predominantly appear epithelioid with round nuclei and abundant granular eosinophilic to clear cytoplasm, although scattered spindle-shaped smooth muscle cells can be seen (*bottom right*). The cells are immunoreactive for **(C)** HMB45 and **(D)** smooth muscle actin.

- Smooth muscle cells typically spindle-shaped but may be polygonal or rounded with epithelioid appearance and abundant eosinophilic cytoplasm
- May show marked nuclear pleomorphism with hyperchromatic nuclei, multinucleated giant cells and necrosis; mitotic figures may be present
- Such findings have no adverse prognostic significance in most cases.
- Immunohistochemical findings include myo-melanocytic reactivity:
 - Melanocytic markers include expression of:
 - HMB-45, melan-A, MART1, tyrosinase, MITF1
 - Myoid markers include expression of:
 - Smooth muscle actin, and less commonly desmin and caldesmon
 - May also be immunoreactive for:
 - CD117 (cytoplasmic) in majority of cases
 - Progesterone receptor and less commonly estrogen receptor
 - CD1a and podoplanin (D2-40)
- Cutaneous angiomyolipoma:
 - Rare benign tumor unrelated to its renal counterpart
 - Not associated with tuberous sclerosis
 - Skin of ear is a common location
 - Usually negative for HMB-45
 - May be considered angioleiomyoma with fat

- Myelolipoma:
 - Tumor-like growth of mature fat and bone marrow elements
 - Often seen in the adrenal gland; rarely seen in extra-adrenal locations, including pelvic (presacral) soft tissues and retroperitoneum
- Myolipoma:
 - Rare variant characterized by proliferation of mature fat and a distinct smooth muscle component
 - Smooth muscle component is immunoreactive for smooth muscle actin and desmin; HMB45 negative.
- Chondroid lipoma:
 - Rare variant composed of mature fat, lipoblasts with bland nuclei, and hibernoma-like cells in myxohyaline pseudochondroid matrix
 - Found in subcutaneous tissue or deep soft tissues of the proximal extremities and limb girdles, especially in adult women
 - Encapsulated with (multi)lobular growth composed of strands and nests of round cells with associated myxochondroid or hyalinized fibrous background
 - Some cells have multiple intracytoplasmic lipid vacuoles resembling lipoblasts
 - Some cells have granular, eosinophilic cytoplasm
 - Highly vascular, often with associated hemorrhage
 - Immunoreactivity includes S100 protein (strongly positive in mature fatty component, weaker in lipoblastic cells, negative in cells without lipoblastic differentiation); rarely cytokeratin positive but EMA negative.
 - Ultrastructural evaluation shows characteristic knob-like cytoplasmic protrusions
 - Reproducible t(11;16)(q13;p13) chromosomal translocation
 - Surgery is curative.
- Intramuscular lipoma:
 - Also referred to as infiltrating lipoma
 - Characterized by the poor circumscription and presence of mature adipocytes infiltrating skeletal muscle
 - Recurs in up to 20% if incompletely excised:
 - Approximately 10% are well-circumscribed, noninfiltrative, and do not appear to recur.
 - Often presents as a slow-growing, deep-seated mass; thigh and trunk most common locations
 - The presence of a deep-seated fatty tumor, a diagnosis of atypical lipomatous tumor, should be excluded.

Differential Diagnosis

- For conventional lipoma:
 - Well-differentiated (lipoma-like) liposarcoma
 - Presence of *MDM2* and *CDK4* immunoreactivity absent in lipomas
 - FISH analysis for *MDM2* gene amplification much more specific than immunohistochemistry in the diagnosis of well-differentiated liposarcoma
- For myxoid lipoma:
 - Myxoid liposarcoma
- For angiomyolipoma:
 - Leiomyosarcoma
 - Carcinoma
 - Sarcoma
- For myolipoma:
 - Other lipomas
 - Leiomyoma with fatty degeneration
- For chondroid lipoma:
 - Myxoid liposarcoma
 - Extraskeletal myxoid chondrosarcoma
 - Cellular pleomorphic adenoma, including epithelial-predominant and/or myoepithelial-predominant

Treatment and Prognosis

- Complete surgical excision is the preferred treatment.
- Prognosis is excellent following surgical removal.
- Local recurrence may be seen and occurs in approximately 5% of cases.

Specific Types of Lipomas

- Pleomorphic and spindle cell lipomas have overlapping clinical and morphologic features and may be regarded as variations of a single entity. Nevertheless, they will be discussed separately.

Pleomorphic Lipoma (Fig. 13-15)

Clinical

- More common in men than in women; occurs over a wide age range from fourth to ninth decades of life with an average age in the sixth decade
- Majority of cases (>80%) occur in the subcutaneous tissue of the posterior neck, shoulder, and back region; 10% develop more anteriorly in the head and neck including face; rarely may occur in the oral cavity
- Typically presents as an asymptomatic, slowly enlarging solitary mass:
 - Freely mobile dermal or subcutaneous mass
 - Often, history is that of a long-standing lesion

Fig. 13-15. Pleomorphic lipoma, posterior neck.

A and B, This variant of lipoma is characterized by an admixture of fat, bundles of collagen, spindle and rounded hyperchromatic cells, and the presence of multinucleated “floret-like” giant cells.

- Rarely, multiple lesions may occur; may be associated with conventional (ordinary) lipoma
- Familial occurrence has been reported.

Pathology

Gross

- Circumscribed, yellow mass usually measuring less than 5 cm but may attain large size, measuring up to 20 cm

Histology

- Characterized by an admixture of fat, thick bundles of birefringent collagen, spindle and rounded hyperchromatic stromal cells, and the presence of multinucleated “floret-like” giant cells
- Giant cells are:
 - A cardinal feature
 - Seen in most but not pleomorphic adenomas
 - Vary from sparse to numerous
 - Composed of cells with multiple marginally placed, overlapping nuclei radially arranged in a

“floret-like pattern” reminiscent of the petals of a flower, and eosinophilic cytoplasm

- Absence of pleomorphic lipoblasts
- Approximately 25% of cases associated with areas typical for spindle cell lipoma (see later):
 - WHO classification is that of spindle cell lipoma/pleomorphic lipoma with an indication that these tumor types represent a common histologic spectrum.
 - Cases with features intermediate between spindle cell lipoma and pleomorphic lipoma occur fairly often.
- Additional findings may include foci of lymphocytes, mast cells, fat necrosis, and dystrophic calcification.
- Immunohistochemistry:
 - Spindle cells and multinucleated cells are CD34 and vimentin positive; may rarely be positive for S100 protein and occasionally desmin
 - Negative for *MDM2* and *CDK4*
- Cytogenetics and molecular genetics:
 - Karyotypes more complicated than those of conventional lipomas:
 - Frequently hypodiploid with multiple partial losses
 - Loss of 16q and 13q material:
 - Loss of 16q13-qter
 - Loss of 13q12 and 13q14-q22
 - Loss of material from 16q more often seen than loss of material from 13q
 - No aberrant *HMG2* expression

Differential Diagnosis

- Liposarcoma, sclerosing

Treatment and Prognosis

- Surgical resection is the preferred treatment and is curative.

Spindle Cell Lipoma (Fig. 13-16)

Clinical

- Many findings similar to those of pleomorphic lipoma
- More common in men than in women; occurs over a wide age range from fifth to eighth decades of life
- Majority of cases occurs on the shoulder or back and posterior neck; other less common sites of occurrence include the extremities, trunk, head, forehead, oral cavity (floor of mouth, hard palate), face, orbit, and nasolabial fold.
- Typically presents as an asymptomatic, slowly enlarging mass:
 - Freely mobile dermal or subcutaneous mass
 - Often, history is that of a long-standing lesion.

Fig. 13-16. Spindle cell lipoma.

A, Circumscribed, yellow, and glistening mass. **B** and **C**, Histologically, this variant of lipoma is characterized by an admixture of small, uniform spindle-shaped cells with associated mature fat cells, ropey-type collagen, and myxoid-appearing stroma. **D**, Spindle cells are CD34 positive.

- Usually are solitary lesions but may be multiple; may be associated with conventional (ordinary) lipomas in other sites

Pathology

Gross

- Usually well-circumscribed, yellow and soft to grayish and rubbery mass measuring less than 5 cm in greatest dimension; a gelatinous or glistening appearance on cut section may be identified.
- May be poorly delineated with extension into the dermis or deeper soft tissues (e.g., subjacent skeletal muscle)

Histology

- Composed of spindle-shaped cells arranged in parallel between univacuolar adipocytes and associated thick rosy collagen:
 - Spindle cell component may be focal or diffuse
 - Sparse to absent mitotic figures

- Myxoid or mucinous-appearing stroma is often present; stromal changes may also include the presence of slit-like cleavage spaces resembling vascular slits (pseudoangiomatous).
- Additional findings include the presence of large numbers in between the spindle-shaped cells; lymphocytes and plasma cells may be present.
- Associated with areas typical for pleomorphic lipoma (see above):
 - WHO classification is that of spindle cell lipoma/pleomorphic lipoma with an indication that these tumor types represent a common histologic spectrum
 - Examples with features intermediate between spindle cell lipoma and pleomorphic lipoma occur fairly often.
- Vascular pattern generally is inconspicuous and composed of small to intermediate-sized thick-walled vessels; a prominent plexiform vascular pattern similar to that seen in myxoid liposarcomas can be found.

- Immunohistochemistry:
 - Spindle cells are CD34 and vimentin positive; may rarely be positive for S100 protein and occasionally desmin
 - Negative for MDM2 and CDK4
 - Absence, actins (smooth muscle and muscle specific) macrophage/histiocytic markers
- Electron microscopy:
 - Abundant rough endoplasmic reticulum, well-formed Golgi apparatus, and non-membrane-bound lipid vacuoles
- Cytogenetics and molecular genetics:
 - Karyotypes more complicated than those of conventional lipomas:
 - Frequently hypodiploid with multiple partial losses
 - Loss of 16q and 13q material:
 - Loss of 16q13-qter
 - Loss of 13q12 and 13q14-q22
 - Loss of material from 16q more often seen than loss of material from 13q
 - No aberrant *HMG A2* expression

Differential Diagnosis

- Peripheral nerve sheath tumor(s)
- Nodular fasciitis
- Dermatofibrosarcoma protuberans
- Liposarcomas, including myxoid and spindle cell types

Treatment and Prognosis

- Surgical resection is the preferred treatment and is curative.

Hibernoma (Fig. 13-17)

Definition: Benign adipose tissue tumor composed at least in part of brown fat cells.

Synonyms: Fetal lipoma; lipoma of embryonic fat; lipoma of immature adipose tissue

Clinical

- Rare tumor
- No gender predilection; may occur over a wide age range but most often occurs in the third decade of life
- Sites of occurrence parallel normal anatomical distribution of brown fat:
 - Typically a subcutaneous mass predilecting to the thigh, scapular and interscapular regions, mediastinum, and upper thorax
 - In the head and neck the most common site of occurrence is the neck.
 - Less common sites of occurrence include the axilla, intrathorax, chest wall, abdominal wall, retroperitoneum, and inguinal region:

Fig. 13-17. Hibernoma.

A and B, This tumor shows an admixture of uniform, round to ovoid, granular eosinophilic cells with distinct cellular membrane and multivacuolated cells with central nuclei and multiple small lipid droplets.

- Myxoid and spindle cell variants tend to be located at the posterior neck and shoulders
 - Approximately 10% are intramuscular.
- Presents as a solitary, slow-growing, painless mass (similar to lipomas)

Pathology

Gross

- Well-defined, mobile, soft mass with a yellow to tan to deep red-brown color; usually measuring between 5 and 10 cm in greatest dimension

Histology

- Lobulated pattern composed of cells showing varying degrees of differentiation:
 - Uniform, round to ovoid, granular eosinophilic cells with distinct cellular membrane

- Multivacuolated cells with central nuclei and multiple small lipid droplets that are oil red-O positive
- Intermixed univacuolar cells with lipid droplets and peripherally displaced nuclei can be identified.
- Prominent vascularity is identified.
- Myxoid variant characterized by the presence of myxoid stroma
- Spindle cell variant characterized by the presence of a spindle cell component with thick collagen bundles, scattered mast cells, and mature adipose tissue:
 - Hybrid lesions with admixture of hibernoma and spindle cell lipoma may be identified.
- Infiltration of underlying muscle can be found.
- Immunohistochemistry:
 - S100 protein positive
 - Typically CD34 negative except for the spindle cell variant, which is CD34 positive (similar to spindle cell lipoma)
 - Uncoupling protein 1 (UCP1) positive
- Cytogenetics and molecular genetics:
 - Abnormalities of the long arm of chromosome 11 (11q13-21)

Differential Diagnosis

- Rhabdomyoma, adult type
- Granular cell tumor

Treatment and Prognosis

- Surgical excision is curative.
- No recurrence following complete excision:
 - All histologic types share similar treatment and prognosis.

Lipoblastoma and Lipoblastomatosis (Fig. 13-18)

Definition: Rare lobulated variant of lipoma occurring almost exclusively during infancy and early childhood, resembling fetal adipose tissue, and occurring in two forms:

- Localized/circumscribed (lipoblastoma)
- Diffuse infiltrating (lipoblastomatosis)

Synonyms: Embryonic lipoma; infantile lipoma

Clinical

- More common in males than females; tumor of infancy usually (>90%) occurring during the first 3 years of life:
 - Some cases occur at birth or in older children.
- Most common in the upper and lower extremities; less common sites of occurrence include the neck, as well as the trunk, mediastinum, mesentery, and retroperitoneum:

Fig. 13-18. Lipoblastoma.

A, The lesion is composed of lipoblasts with myxoid stroma and prominent plexiform vascular pattern. **B,** A multivacuolated lipoblast-like cell is present. This combination of features resembles those associated with myxoid liposarcoma with which lipoblastoma can be confused. Features of lipoblastoma, including occurrence in the first decade of life and absence of nuclear atypia, assist in differentiating it from (myxoid) liposarcoma.

- Other than the neck region, other head and neck sites of occurrence include:
 - Scalp, face, eyelid, cheek, parotid gland, and parapharyngeal region
- Slow-growing, well-circumscribed soft tissue nodule or mass:
 - Lipoblastoma: confined to subcutis or superficial soft tissues resembling a lipoma
 - Lipoblastomatosis: infiltrative growth not only the subcutis but also deeper muscle
- Larger tumors particularly of the head and neck may result in compression of adjacent structures (e.g., airway obstruction and respiratory insufficiency).
- Radiology:
 - Well-delineated soft tissue mass with density of adipose tissue

Pathology

Gross

- Most tumors measure 2 to 5 cm in greatest dimension with a pale yellow color and a myxoid or gelatinous appearance on cut section.

Histology

- Characteristic (multi)lobulated pattern separated by connective tissue septa and mesenchymal areas with loose myxoid appearance:
 - Lobulation less prominent in lipoblastomatosis
 - Entrapped muscle fibers frequently identified in lipoblastomatosis
- Lobules composed of lipoblasts in different stages of development ranging from primitive, stellate, and spindle-shaped mesenchymal cells (so-called preadipocytes) to lipoblasts with univacuolar “signet ring” appearance of mature fat cells:
 - Degree of cellular differentiation may be the same throughout the tumor or vary in different tumor lobules.
- Myxoid or mucoid matrix surround the lipoblasts and prominent plexiform vascular pattern is identified:
 - These features resemble those of myxoid liposarcoma.
- Extramedullary hematopoiesis and cells resembling brown fat may occasionally be identified.
- Cellular maturation with a lipoma-like appearance can be found.
- Adipocytes are S100 protein and CD34 positive.
- Primitive mesenchymal cells are often desmin positive.
- Electron microscopy:
 - Wide morphologic spectrum, including:
 - Immature mesenchymal cells and preadipocytes:
 - Prominent rough endoplasmic reticulum
 - Multivacuolated lipoblasts:
 - Contain numerous vesicles, round to oval mitochondria, and well-developed Golgi apparatus
 - Univacuolated mature lipocytes
- Cytogenetics and molecular genetics:
 - Characteristic cytogenetic abnormality found in the majority of cases is rearrangement of 8q11-13
 - Fusion genes resulting from chromosomal rearrangements include *PLAG1*, a developmentally regulated zinc finger gene, hyaluronic acid synthase 2 (*HAS2*), or collagen 1 alpha 2 (*COL1A2*):
 - *HAS2/PLAG1*
 - *COL1A2/PLAG1*
 - Rearrangement of *HMGA2* rarely reported

Differential Diagnosis

- Myxoid liposarcoma:
 - Rare tumor in the first decade of life
 - Presence of nuclear atypia and absence of pronounced lobular pattern seen in myxoid liposarcoma assist in differentiating it from lipoblastoma/lipoblastomatosis.
- Conventional lipoma
- Hibernoma
- Lipomatosis:
 - Diffuse overgrowth of mature adipose tissue occurring in a variety of clinical settings and affecting different anatomic regions, including:
 - Benign (multiple) symmetric lipomatosis:
 - Rare, idiopathic condition of massive symmetric enlargement of the neck region as a result of fat deposition
 - Synonyms include Madelung disease; Launois-Bensaude syndrome
 - Occurs in middle-aged men often of (but not exclusive to) Mediterranean descent
 - Distribution of fat in the neck region may include cervical neck, preauricular and postauricular, and supraclavicular; non-head and neck areas of involvement may include the axilla and inguinal regions.
 - Not associated with fat deposition elsewhere in the body
 - Presentation is that of nonpainful deformity of involved area:
 - ◻ In the neck the deposition may result in so-called horse collar deformity.
 - ◻ Symptoms associated with fat deposition result from compression of adjacent structures that may include tracheal compression with airway obstruction, and compression on the great vessels of the neck, resulting in signs and symptoms of superior vena caval syndrome.
 - ◻ Patients seek medical attention for cosmetic reasons and/or for relief of symptoms associated with fatty deposition.
 - Cause is unknown but patients may have a history of liver disease and/or excessive alcohol consumption; also may be associated with concomitant diabetes mellitus, gout, and hyperlipidemia.
 - No known genetic or hereditary abnormality
 - Histology includes the presence of nonencapsulated normal-appearing adipose tissue that may include fatty infiltration of adjacent structures.
 - Laboratory (chemical) analysis includes the presence of increased lipid content (as

TABLE 13-4 Benign Peripheral Nerve Sheath Tumors: Clinicopathologic Comparison

	Conventional Schwannoma	Neurofibroma Unassociated with NF1	Neurofibroma in Association with NF1
Gender/age	M = F; 3rd-6th decades	M = F; 3rd-5th decades	M = F; occurs at much younger ages
Common sites	Head and neck; extremities (flexor surfaces), mediastinum, retroperitoneum	Skin and subcutaneous	Cutaneous, deep nerves and viscera
Head and neck sites	Lateral neck, middle ear; less common, oral cavity, SNT, nasopharynx, larynx	Occasionally can be seen in all upper aerodigestive tract sites	Neck, scalp, oral cavity (tongue), and major nerves; other sites of occurrence may include the sinonasal tract, larynx, and salivary glands
Gross	Encapsulated solitary mass; often seen attached to parent nerve	Unencapsulated solitary mass; associated nerve infrequently identified	Unencapsulated, multiple mass lesions; marked distortion of nerve may occur
Histology	Spindle cells seen in cellular (Antoni A) and hypocellular (Antoni B) areas; palisading nuclei (Verocay bodies); prominent thick-walled vessels; degenerative changes are common; scant to no stromal myxoid matrix	Interlacing bundles of spindle cells with wavy or buckled nuclei associated with collagen strands and separated by a myxomatous stroma containing mast cells and lymphocytes	Plexiform type is typical of the disease; proliferation of spindle cells with increase in the endoneurial matrix and separation of the nerve fascicles with associated thick collagen fibers
IHC	Diffuse and intense S100 protein positive	Variable S100 protein staining	Variable S100 protein staining
Association with NF	Uncommon usually occurs sporadically; may be associated with NF2 (especially bilateral acoustic neuromas); rarely associated with NF1	Uncommon	Plexiform (and a lesser degree diffuse) type typical of NF1
Malignant transformation	Rare	Rare	Uncommon, occurring in approximately 2% to 3%

IHC, Immunohistochemistry; NF, neurofibromatosis; SNT, sinonasal tract.

compared with normal fat), in particular, triglycerides

- No effective medical treatment
- Conservative surgical debulking for cosmetic purposes and/or to relief symptoms associated with fatty deposition
 - Asymmetric lipomatosis
 - Pelvic lipomatosis
 - Mediastinoabdominal lipomatosis

Treatment and Prognosis

- Wide surgical excision is the preferred treatment.
- Recurrence reported in 9% to 25%
- Restricted to patients with the diffuse infiltrating type (i.e., lipoblastomatosis)
- Malignant transformation or metastasis does not occur.

BENIGN NERVE SHEATH NEOPLASMS (Table 13-4)

General Considerations

Benign nerve sheath tumors include schwannoma (neu-rilemoma) and neurofibromas.

- Other benign tumors of nerve sheath or presumed peripheral nerve sheath origin include:
 - Granular cell tumor
 - Solitary circumscribed neuroma (palisaded encapsulated neuroma)
 - Dermal nerve sheath myxoma (neurothekeoma)
 - Perineurioma
- Benign nerve sheath tumors of the head and neck are common, perhaps accounting for as many as 45% of all cases:

- Most common site of occurrence is the neck
- Benign nerve sheath tumors of the oral cavity, oropharynx, and nasopharynx are uncommon, accounting for less than 4% of such tumors.
- In the head and neck, schwannomas are more common than neurofibromas.
- Some benign nerve sheath tumors occur in association with neurofibromatosis (see later).
- Represent tumors of neural crest origin or with neuroectodermal differentiation arising in soft tissues including those with nerve sheath differentiation and those arising in association with nerve

Schwannoma

(Figs. 13-19 through 13-21)

Definition: Benign (usually encapsulated) nerve sheath tumor composed of differentiated neoplastic Schwann cells and characterized by cellular component (Antoni A) and loose myxoid component (Antoni B) and presence of diffuse S100 protein immunoreactivity.

Fig. 13-19. Schwannoma.

A, Intraoperatively, the tumor is encapsulated and is attached to the hypoglossal (XII) nerve. **B,** Resected specimen appearing as an encapsulated, tan-white, solid to partly cystic mass attached to an identifiable nerve.

Synonyms: Neurilemoma; benign schwannoma; neurinoma; conventional schwannoma

- 2 clinical, morphologic, and genetically different entities recognized, including:
 - Conventional schwannoma
 - Melanotic schwannoma
- Cellular schwannoma and plexiform schwannoma represent histologic and clinically significant variants.

Clinical

- Most common tumor of peripheral nerves
- Majority (approximately 90%) are solitary and sporadic and not related to neurofibromatosis
- No gender predilection; occur in all ages but most common in the third to sixth decades of life
- Can arise anywhere in the body but predilects to head and neck region, extremities (flexor aspects), as well as mediastinum (posterior; may be referred to as dumbbell tumors as a result of its configuration due to extension into vertebral canal) and retroperitoneum
- Up to 45% of schwannomas present in the head and neck:
 - May occur anywhere but the most common site of occurrence is the neck (lateral aspect) in relation to spinal roots and cervical, sympathetic, and vagus nerves:
 - Sensory nerves are preferred sites of origin but may originate from motor and autonomic nerves.
 - Visceral involvement is rare.
 - Other sites of involvement include the middle ear (referred to as acoustic neuroma, see Section 7 for a more complete discussion) and sinonasal cavity
 - Oral cavity, pharyngeal (oropharynx and nasopharynx) involvement is uncommon:
 - The tongue is the most common site in the oral cavity.
 - May arise in the parapharyngeal space
- Symptoms vary according to site:
 - Neck: solitary, painless mass:
 - Typically, slow-growing neoplasm present for several years prior to diagnosis
 - Oral cavity and pharynx: airway obstruction and dysphagia
 - Pain, paresthesia, or other neurologic symptoms are uncommon.
 - Motor symptoms are uncommon because origin from sensory nerve roots is most common.
- Radiology:
 - MRI:
 - Well-circumscribed heterogeneously enhancing mass
 - May be cystic

Fig. 13-20. Schwannoma.

Typical histology includes **(A)** alternating regions consisting of compact spindle cells (Antoni A areas) arranged in short, interlacing fascicles and loose, hypocellular zones (Antoni B areas). **B**, Hyperchromatic nuclei with elongated and twisted appearance, indistinct cytoplasmic borders, and hyalinized vasculature. **C** and **D**, Nuclear whorling, palisading, or alignment in rows (Verocay bodies). **E**, Diffuse and intense S100 protein immunoreactivity. **F**, Sox10 (nuclear) reactivity.

Fig. 13-21. Schwannoma with degenerative changes (ancient schwannoma).

A, Encapsulated tumor with cystic degeneration and hemorrhage. **B**, Histologically, degenerative changes may include the presence of bizarre-appearing nuclei. **C** and **D**, Schwannoma with increased cellularity (cellular schwannoma); despite increased cellularity there are no features of malignancy. **E**, Neuroblastoma-like schwannoma characterized by the presence of small rounded or spindle-shaped cells with hyperchromatic nuclei and scant cytoplasm, as well as rosette-like structures.

- Etiology:
 - Most conventional schwannomas are sporadic in occurrence with no known cause.
 - Approximately 2% of schwannomas are associated with neurofibromatosis type 2 (NF2 syndrome):
 - Autosomal-dominant disorder caused by germline loss of function of the *NF2* gene located on chromosome 22q12
 - Characterized by multiple conventional schwannomas, meningiomas, and ependymomas
 - In this setting schwannomas often are multiple and/or multifocal
 - Bilateral acoustic neuromas are pathognomonic/ diagnostic feature of NF2 (see later)
 - NF2-associated schwannoma commonly present before 30 years of age
 - In the absence of NF2, multiple conventional schwannoma may be indicative of schwannomatosis:
 - Second most frequent schwannoma-associated disorder
 - Definitive diagnosis predicated on the presence of two or more histopathologically proven conventional or less often plexiform schwannomas and absence of radiographic evidence of vestibular nerve involvement in patients over 18 years of age
 - Presumptive diagnosis made in the presence of two or more histopathologically proven schwannomas:
 - Without symptoms of VIII (vestibular) nerve dysfunction in patients over 30 years of age
 - In an anatomically limited distribution (e.g., single limb or segment of spine) without symptoms of VIII (vestibular) nerve dysfunction in patients of any age
 - Considered to represent a rare genetically distinct disorder
 - No gender predilection
 - Multiple painful cutaneous/subcutaneous or soft tissue nodules
 - May have striking segmental distribution
 - In contrast to NF2 patients, approximately 15% of schwannomatosis cases are familial.
 - Somatic (in tumor) but not germline (normal tissues) mutations of *NF2* gene
 - Identification of *SMARCB1* (*INI1*) gene located centromeric to NF2 on chromosome 22:
 - When mutated predisposes individuals to schwannomatosis
 - Gorlin-Koutlas syndrome:
 - Autosomal-dominant pattern of inheritance:
 - At present, precise genetic defect underlying this syndrome unknown
 - Multiple conventional schwannomas in extended family who also develop multiple nevocytic nevi and vaginal leiomyomas
 - Nevi are congenital, representing earliest manifestations of syndrome
 - Schwannomas and leiomyomas do not appear until adulthood.
 - Radiation induced:
 - Rare occurrence
 - Mean latency of approximately 20 years from time of radiation to development of tumor

Pathology

Gross

- Encapsulated mass often seen attached to an identifiable nerve with a tan-white color, rubbery to firm consistency, and a solid to partly cystic appearance; vary in size but generally measure less than 5 cm in diameter
- Myxoid change may be prominent.

Histology

- Majority of schwannomas of the neck are encapsulated:
 - As a result of these tumors arising in the nerve sheath, the epineurium or perineurium envelops the tumor, creating a true capsule.
- Unlike their soft tissue counterparts, schwannomas of mucosae of the upper aerodigestive tract mucosa, as well as the middle ear, are unencapsulated.
- Composed of alternating regions of compact spindle cells called Antoni A areas, and loose, hypocellular zones called Antoni B areas; in a given tumor, the proportion of these components varies.
- Nuclei are vesicular to hyperchromatic, elongated, and twisted with relatively abundant, slightly eosinophilic cytoplasm with indistinct cytoplasmic borders.
- Cells are arranged in short, interlacing fascicles and whorling or palisading of nuclei may be seen; nuclear palisading with nuclear alignment in rows called Verocay bodies.
- Antoni B areas display a disorderly cellular arrangement, myxoid stroma, and a chronic inflammatory cell infiltrate.
- Increased vascularity is prominent, composed of large vessels with thickened (hyalinized) walls.
- Scattered mitotic figures may be present, but the mitotic rate is low and atypical mitoses are not present.
- Cellular pleomorphism with hyperchromasia can be identified but are not indicative of malignancy.
- Immunohistochemistry:
 - Diffuse and intense S100 protein immunoreactivity (cytoplasmic and nuclear pattern)
 - Leu-7 and glial fibrillary acidic protein (GFAP) may be positive.

- Sox10 (nuclear) staining seen in nearly all schwannomas
- Cytokeratin, actins, desmin, CD34, and epithelial membrane antigen staining are absent.
- Proliferation rate (i.e., MIB-1 staining) is low with staining of 1% to 5% of tumor cell nuclei stain:
 - Low proliferation rates also seen in cellular schwannomas.
- Electron microscopy:
 - Single cell type that includes:
 - Convoluted, relatively thin cytoplasmic processes essentially devoid of pinocytotic vesicles lined by a continuous basal lamina
 - Stromal long-spacing collagen, referred to as Luse body, is commonly identified.
- Cytogenetics and molecular genetics:
 - Loss of expression of neurofibromatosis type 2 (NF2) tumor suppressor gene product termed merlin protein (schwannomin) consistent finding in schwannomas, suggesting a key role in tumorigenesis
 - Underlying loss of merlin expression is inactivation of NF2 tumor suppressor gene located at 22q12
 - Other consistent genetic alterations not identified
- Histologic variants of conventional schwannoma include:
 - Ancient
 - Cellular
 - Plexiform
 - Epithelioid
 - Hybrid schwannoma/perineurioma
 - Microcystic/reticular schwannoma
 - Glandular
 - Neuroblastoma-like

Ancient Schwannoma

- Benign schwannoma with degenerative/retrogressive changes, including cystic degeneration, necrosis, hyalinization, calcification, and hemorrhage may be seen:
 - Pronounced degenerative changes may include bizarre-appearing nuclei characterized by nuclear hyperchromasia and coarse-appearing chromatin
 - Mitoses are generally absent.
 - May occur at any location but tend to be deep seated

Cellular Schwannoma

- Cellularity may vary and some tumors can be very cellular, conferring the designation cellular schwannoma:
 - Composed almost exclusively of Antoni A areas with absence of Verocay bodies

- Demonstrates fascicular growth
- Increased mitotic activity may be present, ranging from one to four mitoses per 10 high-power fields.
- Nuclear hyperchromasia and atypia may be present.
- Strong, diffuse S100 protein staining
- GFAP and Leu-7 may be positive:
 - GFAP may be strong and present in nearly 50% of cases
 - Leu-7 often irregular and patchy and seen in approximately one third of cases
- Rarely may have striking plexiform appearance (plexiform cellular schwannoma)
- Clinical features:
 - Slow growing
 - Tends to occur in retroperitoneum, paravertebral region of mediastinum, pelvis, or intraspinal space:
 - May also occur frequently in the head and neck and extremities
 - Often arises from major nerve
 - Usually encapsulated but may be focally infiltrative, including erosion of bone
 - Typically lacks association with NF1, although occasionally associated with neurofibromatosis
 - May recur if incompletely excised but do not metastasize

Plexiform Schwannoma

- Histologic variant characterized by:
 - Plexiform or multinodular growth pattern
 - Each nodule is encapsulated.
 - Composed mainly of Antoni A areas; mitoses may be present
 - Infrequently multicentric
 - Clinical features:
 - Predilection in skin or subcutaneous tissue of the extremity, head and neck, and trunk
 - Tend to affect younger patients than conventional schwannoma
 - With rare exceptions not associated with NF1 and NF2:
 - Contrasts with plexiform neurofibroma
 - In approximately 5% of cases associated with NF2; occasional cases reported in schwannomatosis
 - Congenital/childhood plexiform cellular schwannoma:
 - Recently described
 - Initially thought to possibly be a congenital neural hamartoma
 - No gender predilection
 - >50% present in infancy; >40% congenital
 - Most involve skin and subcutaneous tissue; may also occur in retro-orbit and pelvis

- May be large (>5 cm)
- Histologic findings:
 - Hypercellular, variably hyperchromatic spindle-shaped proliferation
 - Arranged in fascicles, sheets, micronodules, or lobules
 - Mitoses commonly identified:
 - Some reported cases with more than 30 mitoses per 10 high-power fields
 - Atypical mitoses not seen
 - May be well circumscribed but may also show pushing and/or infiltrative margins
 - Lack of epithelioid morphology, anaplasia, and necrosis
- Immunohistochemistry:
 - Cells uniformly S100 protein positive
 - EMA may be positive in peripheral lining cells
 - Increased proliferation rate by Ki67 (MIB1) staining may be present:
 - Some reported cases with greater than 30% proliferation rate
- Tend to recur or persist
- Do not metastasize

Epithelioid Schwannoma

- Mainly occur in adults in deep dermis and subcutis of the limbs:
 - May occur in viscera (gastrointestinal tract [colon] and genitourinary tract [bladder])
 - Rare in head and neck
- Typically encapsulated:
 - Lack Antoni A or B zonation or hyaline vessels
 - Consists of nests or trabeculae of eosinophilic epithelioid cells
 - Cells have uniform round to oval nuclei with frequent intranuclear pseudoinclusions and eosinophilic fibrillary cytoplasm.
 - Mitoses are not seen.
 - Diffusely S100 protein positive; CD34 reactivity may be identified
 - Cytokeratins and EMA negative

Hybrid Schwannoma/Perineurioma

- Represents the most common type of hybrid peripheral nerve sheath tumor:
 - Defined as one of the major benign peripheral nerve sheath tumors (BPNST) containing a histologic component typical of another
 - Other less common hybrid PNSTs include:
 - Hybrid neurofibroma/perineurioma
 - Hybrid neurofibroma/schwannoma
- Hybrid schwannoma/perineurioma represents a BPNST mainly consisting of Antoni A areas (without palisading or hyaline vessels) and a marked whorled growth pattern

- Primarily occurs in adults
- Usually occurs in somatic soft tissue
- Immunoreactivity for S100 protein and EMA

Microcystic/Reticular Schwannoma

- Rare morphologic variant
- Primarily occurs in adults
- Predilection to arise in gastrointestinal tract
- Characterized by anastomosing and intersecting strands of eosinophilic spindle-shaped cells arranged in islands of myxoid or collagenous stroma

Glandular Schwannoma

- Nerve sheath tumor with focal glandular differentiation
- Controversial entity as most nerve sheath tumors with glandular differentiation are malignant (malignant peripheral nerve sheath tumor):
 - Appears that rare benign peripheral nerve sheath tumors with glandular differentiation reported but the glandular component may represent entrapped nonlesional, normal structures

Neuroblastoma-Like Schwannoma

- Predilects to the superficial soft tissues of the neck, palm, and flank
- Histologically, has a fibrous capsule with areas of typical neurilemoma as well as neuroblastoma-like areas:
 - Neuroblastoma-like areas are composed of sheets or nests of small rounded or spindle-shaped cells with central hyperchromatic nuclei and scant cytoplasm
 - Rosettes and pseudorosettes are identified:
 - Rosettes are perivascular or surround central cores of radiating spokes of collagen
 - Focal areas of conventional schwannoma can be found.
 - Scarce mitotic activity; necrosis and hemorrhage are absent

Melanotic Schwannoma (MS)

- Otherwise typical schwannoma but uniquely characterized by presence of intracytoplasmic melanin pigment:
 - Tend to occur in patients a decade younger than conventional schwannomas
 - Tumors tend to be cellular and unencapsulated.
 - Composed of closely packed, pigmented, spindle-shaped, and epithelioid cells arranged in short fascicles or nests:
 - Tumor cells with round nuclei, distinct small nucleoli, striking nuclear grooves, and eosinophilic to amphophilic cytoplasm
 - Multinucleated cells may occasionally be present.

- Schwann cells contain intracytoplasmic brown to black melanin pigment.
- Fontana positive
- Immunoreactivity for S100 protein, HMB45, and melan-A
- Melanosomes identified ultrastructurally
- May be divided into non-psammomatous and psammomatous variants:
 - 50% contain psammoma bodies (psammomatous melanotic schwannomas)
 - Approximately 50% of patients with psammomatous melanotic schwannomas have Carney complex, which is an autosomal-dominant multiple endocrine and lentiginous syndrome characterized by:
 - Cardiac myxoma as well as myxomas of the skin and breast
 - Lentiginous (spotty) pigmentation
 - Endocrine abnormalities including Cushing syndrome associated with multinodular adrenal hyperplasia and acromegaly due to pituitary adenoma
 - Congenital osteochondromyxoma
 - Two genetic loci identified:
 - One on chromosome 17q22-24 (CNC1) at the site of *PRKAR1A* gene, the tumor suppressor gene mutated in about 50% of CNC kindreds
 - One on chromosome 2p16 (CNC2)
- A small proportion of melanotic schwannomas (with or without psammoma bodies) have low-grade malignant potential with metastases:
 - May metastasize to:
 - Lung, stomach, liver, adrenal gland, and brain
 - Brain metastases often fatal
 - Metastases usually occur after initial local recurrence.
 - Often arise from sympathetic chain or nonaxial locations
 - No pathognomonic features of malignancy but malignant ones tend to have:
 - Large vesicular nuclei with scant chromatin
 - Prominent eosinophilic or violaceous (macro) nucleoli
 - Increase mitoses including atypical mitoses
 - Broad zones of necrosis
 - Histology of primary tumor may appear deceptively bland.
 - Distinction from metastatic melanoma may be difficult.
 - Surgical excision to include tumor-free margins is treatment for melanocytic schwannomas.
 - Recent evidence purports that melanotic schwannomas are distinctive malignant tumors rather than benign neoplasms with occasion-

ally unpredictable behavior proposing reclassification as malignant melanotic schwannian tumor:

- 26 of 40 cases reported with adequate follow-up included:
 - 35% recurred and 44% metastasized
 - 54% alive without disease, 19% alive with disease, and 27% died of disease
- Gene expression profiling showed significant differences between MS, melanoma, and conventional schwannoma.
- Loss of *PRKAR1A* expression suggested link to Carney complex even when this history was absent.

Differential Diagnosis

- For conventional schwannoma:
 - Neurofibroma (see later and [Table 13-4](#))
 - Leiomyoma
 - Meningioma
 - Solitary fibrous tumor
 - Fibrous histiocytoma
 - Synovial sarcoma, monophasic
- For cellular schwannoma:
 - Malignant peripheral nerve sheath tumor
 - Leiomyosarcoma
 - Fibrosarcoma
- For melanotic schwannoma:
 - Malignant melanoma
- For glandular schwannoma:
 - Malignant peripheral nerve sheath tumor
- For neuroblastoma-like schwannoma:
 - Neuroblastoma
 - Primitive neuroectodermal tumor

Treatment and Prognosis for Conventional Schwannoma and Histologic Variants (Except for Melanotic Schwannoma)

- Surgical excision is the preferred treatment:
 - Every effort should be made to preserve the integrity of the nerve from which the tumor arises.
 - In cases in which the complete excision would result in damage or sacrifice of the parent nerve, incomplete excision can be performed.
- Local recurrences are infrequent.
- Prognosis is excellent following surgical removal:
 - Malignant transformation is extremely rare.

Neurofibroma

Definition: Well-demarcated but unencapsulated intra-neural or diffusely infiltrative extraneural tumor consisting of an admixture of Schwann cells, perineurial cells, and fibroblasts; residual interspersed myelinated and unmyelinated axons embedded in extracellular matrix.

Fig. 13-22. Solitary neurofibroma.

A, Neurofibroma appearing as a circumscribed, unencapsulated, tan-white to gray mass. **B**, Histologically, the neoplasm is submucosal and unencapsulated, composed of interlacing bundles and haphazardly arranged spindle-shaped cells. **C**, At higher magnification, the nuclei appear wavy or buckled and are loosely arranged in a collagenized to myxomatous stroma; wire-like strands of collagen ("shredded carrots") are present; stromal inflammatory cells including lymphocytes and mast cells are present. **D**, S100 protein positive but reactivity tends to be less striking as compared with schwannomas.

NOTE: In mucosal sites, schwannomas may also be unencapsulated.

- Occurs as solitary, diffuse, or plexiform lesions with varying clinical and pathologic findings

Solitary Neurofibroma

(Table 13-4, Fig. 13-22)

Definition: Localized, benign peripheral nerve sheath tumor composed principally of Schwann cells:

- Appear to originate within endoneurium:
 - Presence of mixed cell population in conjunction with apparent endoneurial origin raise doubts relative to its being a neoplasm and perhaps better considered a hamartomatous lesion
- Small subset entirely intraneural

Synonym: Localized (sporadic) neurofibroma

Clinical

- Is more common than diffuse or plexiform neurofibromas

- No gender predilection; most commonly occurs in the third to fourth decades of life
- May affect any part of the body but are found most commonly in the skin and subcutaneous tissue
 - Occasionally, can be seen in all upper aerodigestive tract mucosal sites
 - Rarely may occur in deep soft tissue often in axial location
- Presentation is most often that of a solitary, painless (cutaneous) mass; usually slow-growing, developing over years
- Occurs sporadically; not associated with neurofibromatosis (NF):
 - Multiple neurofibromas typically are associated with NF1 (see Neurofibromatosis later in chapter)
 - Solitary neurofibromas of deep soft tissues more often associated with NF1 and have a small risk of undergoing malignant transformation

- Multiple NFs:
 - Presence of small number of cutaneous NFs:
 - May occur in patients without stigmata of NF1 but in this situation a diagnosis of NF1 should be excluded

Pathology

Gross

- Circumscribed but unencapsulated, nodular to polypoid, rubbery to firm, tan-white to gray-appearing glistening mass:
 - Neurofibromas result from a diffuse increase in the endoneurial matrix with proliferation and distortion of Schwann cells and axons, resulting in an unencapsulated neoplasm.
- Involved nerve occasionally may be identified entering and exiting from the tumor, which expands the nerve in a fusiform manner:
 - In this setting, confinement to within the endoneurium results in an encapsulated tumor.

Histology

- Nonencapsulated lesion composed of interlacing bundles of spindle-shaped cells with hyperchromatic nuclei having a wavy or buckled appearance loosely arranged in a variable fibromyxoid stroma:
 - Myxomatous stroma may be:
 - Focal and limited in extent
 - Extensive and diffuse:
 - Typically occurs in extremities and histochemically contains abundant pools of acid mucopolysaccharides
 - May be so prominent as to suggest a diagnosis of myxoma:
 - Presence of S100 protein would differentiate it from myxoma
 - Collagenized stroma may include:
 - Wire-like strands of collagen (likened to “shredded carrots”)
 - Dense collagen bundles
- Stromal inflammatory cells include mast cells and lymphocytes; xanthomatous cells can be identified.
- Cellularity varies, including hypercellular tumors (cellular neurofibromas) and hypocellular tumors with a prominent myxoid change.
- Some tumors may have atypical nuclei and may be referred to as neurofibroma with atypical features:
 - Include nuclear pleomorphism with marked hyperchromasia (similar to nuclei seen in ancient schwannoma)
 - Usually atypical features are focally identified
 - Insufficient features (i.e., increased cellularity and mitotic activity) for a diagnosis of a low-grade malignant peripheral nerve sheath tumor

- Similar atypia in patients with NF1 should seriously raise concern for the possibility of malignant change:
 - Presence of mitoses as well as nuclear atypia and increased cellularity in this setting considered by some authorities as evidence of malignancy
 - Molecular analysis suggests that such lesions in patients with NF1 are premalignant.
- Mitotic activity is rare to absent; necrosis and hemorrhage not identified
- In contrast to schwannomas blood vessels lack hyalinization.
- Immunohistochemistry:
 - S100 protein positive but less striking as compared with benign schwannomas:
 - In NF proportion of S100 protein-positive cells ranges from 30% to 50%
 - S100 protein in benign schwannomas is almost 100% positive.
 - Epithelial membrane antigen (EMA) negative (except in residual perineurium)
 - Sox10 (nuclear) staining seen in more than 90% of cases
 - Perineurial cells are immunoreactive for EMA, glucose transporter 1 (GLUT1), and claudin-1
 - Stromal cells are CD34 positive.
- Electron microscopy:
 - Mixture of cell types:
 - Spindle (perineurial-like) cells: thin, long, attenuated bipolar cytoplasmic processes, pinocytotic vesicles, and discontinuous basal lamina
 - Cells with features characteristic of Schwann cells, including convoluted, cytoplasmic processes essentially devoid of pinocytotic vesicles lined by a continuous basal lamina
- Histologic variants of solitary NF considered rare and include:
 - Epithelioid NF:
 - Round cells with eosinophilic cytoplasm
 - Granular cell NF:
 - Cells with granular eosinophilic cytoplasm:
 - Intracytoplasmic diastase-resistant, PAS-positive material
 - Pigmented NF:
 - Rare tumor type that can be associated with NF1
 - Most often are of the diffuse-type neurofibroma but some tumors may have features of diffuse and plexiform neurofibromas
 - Pigmented cells dispersed throughout the lesion but with a tendency to cluster in more superficial aspects
 - Pigmented cells are immunoreactive for S100 protein and melanocytic markers

Differential Diagnosis

- Schwannoma (see above and Table 13-4)
- Myxoma:
 - In contrast to myxoma, myxomatous neurofibromas have a greater degree of cellular orientation, a more prominent vascular pattern, and S100 protein immunoreactivity.
- Perineurioma (see later)

Treatment and Prognosis

- Simple surgical excision is the preferred treatment and is curative.
- Risk for malignant transformation is extremely low.

Plexiform Neurofibroma

(Figs. 13-23 and 13-24)

Definition: Benign peripheral nerve sheath neoplasm with characteristic clinical and pathologic features found almost exclusively in patients with neurofibromatosis 1 (NF1):

- Generally regarded as pathognomonic for NF1 even in the absence of other stigmata at time of presentation

Clinical

- No gender predilection; generally occurs early in childhood
- May occur in any location but tendency to occur in the head and neck, back, and inguinal region:
 - In the head and neck, common sites of occurrence include:
 - Neck, scalp, oral cavity (tongue), and major nerves
 - Other sites of occurrence may include the sino-nasal tract, larynx, and salivary glands.
- Presentation includes cosmetic deformity, enlarging mass lesion, and functional impairments of the site of involvement:
 - Lingual involvement:
 - May produce macroglossia with functional impairment
 - Usually occurs in children under 3 years of age
- Involvement of major nerves leads to nodular or fusiform enlargement that is poorly circumscribed, forming a tortuous appearance along segments of the nerve; a characteristic appearance termed “bag of worms” or “string of beads” results:
 - Involvement of the entire extremity termed “elephantiasis neuromatosa”
- Radiology:
 - CT scan:
 - Well-defined oval to spheric to fusiform lesion centered at the anatomic location on a peripheral nerve, cranial nerve, or other nerves

- Often, there is a family history of NF1:
 - Presence of plexiform neurofibroma strictly correlates to and is virtually pathognomonic of NF1 (see neurofibromatosis later in this section)
 - Some patients with plexiform neurofibromas may have NF2.
 - Some patients with small solitary plexiform neurofibromas may not have neurofibromatosis.

Pathology

Gross

- Ill-defined, elongated, nodular, or multinodular growth or cylindric enlargement of the involved nerve:
 - Due to containment within the perineurium the appearance has been likened to a bag of worms or string of beads
 - Alternative appearance, especially when a large nerve trunk is involved, may be that of ropey enlargement of the involved nerve

Histology

- Tortuous expansion of the nerve with:
 - Increase in the endoneurial matrix with separation of the nerve fascicles
 - Disorderly proliferation of Schwann cells, fibroblasts, and axons with associated thick collagen fiber
 - Perineurial fibrous thickening
- With continued growth, cellular extension into adjacent soft tissues may occur, resulting in a lesion with mixed plexiform and diffuse areas.
- Hybrid lesions with clinicopathologic features of plexiform NF and diffuse NF not uncommon
- Hybrid lesions of plexiform NF and schwannoma occasionally occur.
- Mitotic activity:
 - Presence of mitotic activity generally in association with increased cellularity and nuclear atypia felt to be indicative of malignant transformation (i.e., malignant peripheral nerve sheath tumor)
- Immunohistochemistry:
 - Variably S100 protein and Leu-7 positive
- Electron microscopy:
 - Mixture of cell types:
 - Predominant cell has features characteristic of Schwann cells, including convoluted, cytoplasmic processes essentially devoid of pinocytotic vesicles lined by a continuous basal lamina
 - Fibroblastic cells are numerous, characterized by prominent endoplasmic reticulum lacking basal lamina.

Differential Diagnosis

- Schwannoma conventional and plexiform types (see Table 13-4)

Fig. 13-23. Plexiform neurofibroma.

A, Marked facial deformity due to plexiform neurofibromas in this man with neurofibromatosis. **B** through **D**, Histology of soft tissue and intraparotid plexiform neurofibromas showing tortuous expansion of the nerves with increase in the endoneurial matrix with separation of the nerve fascicles, disorderly proliferation of Schwann cells, fibroblasts, and axons with associated thick collagen fiber and perineurial fibrous thickening. **E**, Pigmented neurofibroma is characterized by the presence of melanin containing cells (S100 protein and melanocytic markers positive, not shown); pigmented cells are dispersed throughout the lesion but tend to cluster in more superficial aspects. Pigmented neurofibromas most often occur in the diffuse-type neurofibroma, but in some tumors there may be features of both diffuse and plexiform neurofibromas.

Fig. 13-24. Malignant transformation.

Malignant transformation of plexiform neurofibroma in neurofibromatosis. **A**, Intraneural and **(B)** infiltrative growth. Malignant transformation includes the presence of hypercellularity, cellular atypia, and increased mitotic activity.

- Mucosal neuroma (see later)
- Neurothekeoma (see later)

Treatment and Prognosis

- Surgery is the preferred treatment:
 - Conservative surgical resection for cosmesis, as well as preservation of nerve function, is advocated, if possible
 - Complete tumor resection is possible in patients with small tumors (measuring less than 5 cm)
 - Management compromised in patients with larger tumors (measuring greater than 5 cm) given tendency to local recurrence due to diffuse spread of the lesion along the course of the nerve
- Patients with head and neck plexiform neurofibroma are more likely to benefit from surgery for one (or more) of the following indications:
 - Exclude malignancy in a rapidly enlarging mass

- Provide relief from neurogenic pain or motor weakness
- Improve symptoms caused by airway compression
- Enhance cosmesis in those with disfiguring disease
- Metastatic disease generally does not occur.
- Increased morbidity related to local recurrence
- Malignant transformation:
 - Occurs in plexiform neurofibromas associated with NF1
 - Occurs in approximately 2% to 3% of NF1 patients
 - Peak incidence in third decade of life
 - Occurs most often in deep-seated, large centrally located tumors
 - Malignant transformation would necessitate radical surgical extirpation.

Diffuse Neurofibroma

Definition: Uncommon, histologically distinct form of neurofibroma generally not associated with neurofibromatosis.

Synonym: Paraneurofibroma

Clinical

- No gender predilection; occurs principally in children and young adults (second and third decades)
- Primarily occurs in the trunk and skin of the head and neck:
 - Other less frequent sites of occurrence include the orbit and gastrointestinal and genitourinary tract.
- Presents as a solitary, ill-defined, plaquelike subcutaneous mass
- Majority of patients with diffuse neurofibroma do not have neurofibromatosis:
 - 10% of patients have NF1.

Pathology

Gross

- Poorly defined, glistening to gelatinous-appearing nodular mass ranging in size from 0.5 to greater than 6 cm.

Histology

- Infiltrative (but not destructive) lesion with extension throughout soft tissues enveloping structures such as nerves and cutaneous adnexal structures:
 - Infiltrates along connective tissue septa and envelops rather than destroys normal structures
- Shares histologic features of conventional neurofibroma but differs in that:
 - Schwann cells are less elongated with fusiform or round contours with indistinct cytoplasm
 - Has a uniform matrix of fine fibrillary collagen

- Has presence of meissnerian differentiation, a characteristic finding of this lesion
- Constituent nerves appear markedly hypertrophic and edematous.
- Pigmented (melanin-containing) dendritic cells not uncommonly present
- Multinucleated giant cells may be present.
- Other mesenchymal components including mature fat and large ectatic blood vessels may be prominently identified; lesions with these findings tend to be more commonly seen in association with NF1.
- Nuclear palisading may rarely be present.
- Immunohistochemistry:
 - S100 protein positive in many but not all cells
 - CD34 negative

Differential Diagnosis

- Spindle cell lipoma
- Dermatofibrosarcoma protuberans (DFSP), including pigmented form (also referred to as Bednar tumor), differs from diffuse neurofibroma (nonpigmented and pigmented types) by:
 - Presence of storiform growth with uniform fibroblastic cells
 - Expression of CD34 but absence of S100 protein staining

Treatment and Prognosis

- Surgical excision is the preferred treatment:
 - Due to infiltrative type growth, may be difficult to completely excise
- Tendency to local recurrence as a result of difficulties in complete surgical resection
- Rarely undergoes malignant transformation

Granular Cell Tumor

Definition: Benign tumor showing neuroectodermal differentiation composed of large oval to round cells with abundant eosinophilic granular cytoplasm.

Synonyms: Granular cell myoblastoma; granular cell neuroma; granular cell schwannoma; granular cell neurofibroma; Abrikossoff tumor; granular cell schwannoma

- Two forms can occur:
 - Mucosal granular cell tumor
 - Congenital granular cell epulis

Mucosal Granular Cell Tumor

- See Section 4, Larynx, for a more complete discussion, including illustrations.

Congenital Granular Cell Epulis

- See Section 5, Oral Cavity, for a more complete discussion, including illustrations.

Solitary Circumscribed Neuroma (Palisaded Encapsulated Neuroma)

- Benign peripheral nerve sheath tumor composed of Schwann cells, axons, and perineurial fibroblasts
- See Section 2, Oral Cavity, for a more complete discussion, including illustrations.

Mucosal Neuroma

- Benign lesion of nerve sheath origin involving mucosal surfaces of the oral cavity, eyelids, and intestines occurring associated with multiple endocrine neoplasia (MEN) syndrome type 2B
- See Section 2, Oral Cavity, for a more complete discussion, including illustrations.

Nerve Sheath Myxoma (Fig. 13-25)

Definition: Benign, usually cutaneous, histologically distinctive predominantly myxoid neoplasm presumably of nerve sheath (Schwann cell) origin.

Clinical

- No gender predilection; occur over a wide age range (first to eighth decades) but primarily occur in young and middle-age adults
- Predilection for the distal extremities (85% of cases)
 - Hands and fingers more common
 - Other common sites include knee, lower leg, ankle, and foot.

Fig. 13-25. Neurothekeoma.

Dermal nerve sheath myxoma (myxoid classic neurothekeoma) characterized by a lobular, well-circumscribed proliferation of spindle-shaped or rounded (epithelioid) cells in abundant myxoid matrix. S100 protein immunoreactivity was present (not shown).

- Trunk and head and neck involvement infrequent:
 - Rarely, seen in the oral cavity (tongue, lip) and external auditory canal
- Presentation is that of a solitary, slowly growing mass.
- No known association with neurofibromatosis
- Previously, nerve sheath myxoma and neurothekeoma were considered related lesions; however:
 - Distinct gene expression profiles for nerve sheath myxomas and neurothekeomas substantiate that these are separate entities.
 - Molecular data confirm that dermal nerve sheath myxomas are of peripheral nerve sheath origin and suggest that neurothekeomas may be a variant of fibrous histiocytomas.

Pathology

Histology

- Characterized by a lobular or multinodular, well-circumscribed but unencapsulated proliferation of admixed spindle-shaped or rounded (epithelioid) cells separated by scant collagen set in abundant myxoid matrix:
 - Spindle neoplastic cells arranged in nests, cords, and syncytial-like aggregates in fascicles or whorls
 - Composed of spindle-shaped, epithelioid, ring-like, and stellate cells
 - Nuclei tend to have vesicular chromatin but may be hyperchromatic or pleomorphic with eosinophilic cytoplasm:
 - Some cells may be multivacuolated and have spider-like processes.
 - Usually no significant increase in mitotic activity but occasional cases may have increased mitotic activity; atypical mitoses are not present
 - Myxoid matrix is composed of hyaluronic acid or sulfated acid mucins.
- Immunohistochemistry:
 - Diffusely S100 protein positive
 - GFAP, CD57 (Leu-7), and NSE reactive
 - Vimentin positive
 - Collagen type IV present around tumor cells
 - EMA-positive perineurial cells can be found in fibrous capsule.
 - Occasional CD34-positive intraneural fibroblasts may be present.
- Electron microscopy:
 - Spindle-shaped cells have features supportive of Schwann cells:
 - Cells with convoluted, cytoplasmic processes essentially devoid of pinocytotic vesicles lined by a continuous basal lamina

Differential Diagnosis

- (Cellular) neurothekeoma
 - Unrelated to nerve sheath myxoma
 - Although not completely proven, increasing evidence supports tumor within the spectrum of fibrohistiocytic tumors.
 - In contrast to nerve sheath myxoma:
 - More common in women than in men
 - Occurs primarily in children and young adults:
 - Wide age range but majority of cases occurs in the first two decades of life
 - Cutaneous (dermal and subcutaneous)-based tumors
 - Commonly involves head and neck, upper extremities, and shoulder region
 - Histology:
 - Multilobular, micronodular, or plexiform growth consisting of tumor nests circumscribed by bands of densely hyalinized collagen; whorling growth pattern frequently presents within individual tumor nests
 - Composed of epithelioid to slightly spindle-shaped cells with ovoid nuclei, indistinct nucleoli, and ample amount of slightly eosinophilic cytoplasm
 - Generally lack significant nuclear pleomorphism but rarely may have focal marked cytologic atypia
 - Increased mitotic activity may be present but usually less than 5 mitoses per 10 high-power fields; atypical mitoses usually absent
 - Myxoid stromal change frequently present and may be prominent:
 - When myxoid stroma is prominent, it may suggest a diagnosis of nerve sheath myxoma.
 - Immunohistochemistry:
 - S100 protein negative
 - GFAP usually but not always negative
 - MITF1 positive
 - Treatment includes complete excision.
 - May recur if incompletely excised
- Neurilemoma
- Neurofibroma
- Leiomyoma
- Myxoma
- Fibrohistiocytic lesions
- Neuroid nevus

Treatment and Prognosis

- Conservative but complete surgical resection is the preferred treatment.
- Local recurrence occurs because of inadequate excision.
- No malignant potential

Perineurioma (Fig. 13-26)

Definition: Benign tumor composed of perineurial cells occurring intraneurally and as a soft tissue lesion, the latter unassociated with a nerve.

Clinical

- Rare tumor(s) of all sites
- All perineuriomas are rare in head and neck sites.
- Most common genetic abnormality involves chromosome 22 but no known association with neurofibromatosis, although very rare examples reported in patients with NF1 or NF2
- Several forms are recognized, including:
 - Soft tissue (extraneural) perineurioma
 - Intraneural perineurioma
 - Sclerosing perineurioma
 - Reticular perineurioma
- Soft tissue perineurioma:
 - Previously referred to as storiform perineurial fibroma
 - Recognized as a distinctive type of nerve sheath tumor
 - More common than intraneural perineurioma
 - More common in women than men; occurs in adults:
 - Primarily affects soft tissues of the extremities and shoulder girdles:
 - Approximately 30% occur in deep soft tissue
 - Rarely occur in visceral sites
 - Present as a discrete, solitary, painless superficial nodule
- Intraneural perineurioma:
 - Benign neoplasm previously referred to as localized hypertrophic neuropathy
 - No gender predilection; adolescence and early adulthood
 - Primarily affects peripheral nerves of the extremities
 - Associated with motor neurologic deficits including progressive muscle weakness with or without atrophy; sensory disturbances are less common.
- Sclerosing perineurioma:
 - Benign nonrecurring neoplasm
 - No gender predilection for males; young adults
 - Typically affects skin of hand (finger and palm)
- Reticular perineurioma:
 - Predilection for women; adults (fourth to seventh decades; mean, 23 years)

Pathology

Gross

- Soft tissue perineurioma:
 - Well-circumscribed but not encapsulated, lobulated, firm, gray-white-appearing mass usually

measuring between 1 and 7 cm in greatest dimension but also may attain larger sizes

- Usually solitary but multinodular examples occur
- No apparent nerve association
- Intraneural perineurioma:
 - Segmental, sausage-shaped, tubular enlargement of an often but not always affected nerve
 - Usually measures less than 10 cm in greatest dimension but may reach large sizes
 - Appearance similar to plexiform neurofibroma (i.e., “bag of worms”) is not identified.
- Sclerosing perineurioma:
 - Circumscribed but not encapsulated solitary small nodule usually located in dermis

Histology and Immunohistochemistry

- Soft tissue (extraneural) perineurioma:
 - Composed of elongated, slender, spindle-shaped, or wavy cells arranged in short bundles, fascicles, or lamellae to looser whorls or storiform patterns embedded in collagen fibers
 - Cells have elongated, wavy-appearing nuclei with tapered ends, inconspicuous nucleoli, and elongated bipolar cytoplasmic processes
 - Aggregates of collagen fibers can be seen to be encircled by elongated tumor cell processes
 - Myxoid matrix often present (focal > diffuse)
 - Rare to absent mitoses; pleomorphism and necrosis are absent
 - Entrapment or infiltration of surrounding fat and skeletal muscle may occur.
 - Immunohistochemistry:
 - Epithelial membrane antigen (EMA) positive
 - Claudin-1 and GLUT1 often positive
 - CD34 positive in approximately 50% to 60% of cases often more diffuse than EMA
 - S100 protein negative (may focally be present)
 - Collagen 4 and laminin positive
- Intraneural perineurioma:
 - Proliferation of perineurial cells throughout the endoneurium forming concentric multiple layers around nerve fibers referred to as pseudo-onion bulbs:
 - Distinctive architectural feature best seen on cross-section
 - Large whorls may envelop large nerve fibers.
 - Mitotic activity is rare.
 - Immunohistochemistry:
 - EMA positive (membranous and diffuse)
 - Claudin-1 and GLUT1 often positive
 - S100 protein negative
 - Collagen 4 and laminin positive
- Sclerosing perineurioma:
 - Histologic variant characterized by increased sclerosis

Fig. 13-26. Perineurioma.

A, Soft tissue (extraneural) perineurioma composed of elongated, slender, spindle-shaped, or wavy cells arranged in short fascicles within a collagenized stroma. **B**, Cells have elongated, wavy-appearing nuclei with tapered ends, inconspicuous nucleoli, and elongated cytoplasmic processes. **C** and **D**, Soft tissue (extraneural) reticular perineurioma showing tumor cells arranged in a net-like fashion around ground substance; slender cell processes can be seen. **E**, Neoplastic cells are EMA positive characterized by membranous staining pattern. **F**, Intraneural perineurioma in which there is a proliferation of perineurial cells throughout the endoneurium forming concentric multiple layers around nerve fibers (pseudo-onion bulb).

Fig. 13-26, cont'd

G and **H**, Sclerosing perineurioma is a histologic variant characterized by increased sclerosis; cells are arranged in cords and trabeculae and have a rounded appearance.

- Cells are arranged in cords and trabeculae and have a spindle-shaped to rounded (epithelioid) appearance.
- EMA positive; actins and keratins may be positive.
- S100 protein negative
- Reticular perineurioma
 - Net-like or lace-like pattern arrangement of cells of growth
 - Results in formation of prominent cystic or microcystic change
 - Most reticular tumors have foci of “conventional” perineurioma.
 - Aside from this appearance shares similar findings to “conventional” perineurioma
- Cytogenetics and molecular genetics:
 - Abnormalities of chromosome 22 (deletion, partial or complete):
 - Not considered diagnostically specific as found in other soft tissue tumors, including benign schwannomas
- For sclerosing perineurioma
 - Sclerosing adnexal tumor
 - Epithelioid neurofibroma and schwannoma
 - Epithelioid hemangioendothelioma
 - Epithelioid sarcoma
- For reticular perineurioma
 - Myoepithelial tumors of soft tissue
 - Dermatofibrosarcoma protuberans

Treatment and Prognosis

- Surgical resection is the preferred treatment and is curative.
- Rarely recur
- Rare malignant perineuriomas exist (perineurial malignant peripheral nerve sheath tumor):
 - Show features similar to soft tissue perineurioma but with hypercellularity, nuclear atypia, hyperchromasia, and high mitotic rate
 - May recur and/or metastasize but appear to behave less aggressively than conventional peripheral nerve sheath tumor
 - Not associated with neurofibroma or occurring in patients with NF1

Differential Diagnosis

- For dermal soft tissue perineurioma
 - Neurofibroma
 - Dermatofibrosarcoma protuberans
 - Extracranial meningioma
- For deep soft tissue perineurioma
 - Solitary fibrous tumor
 - Fibromatosis
 - Cellular myxoma
 - Low-grade fibromyxoid sarcoma
 - Low-grade myxofibrosarcoma

Neurofibromatoses

Definition: Two clinically distinct autosomal-dominant inherited disorders caused by two separate abnormal genes characterized by a variety of lesions, including those of the nervous system:

- Two disorders include neurofibromatosis 1 (NF1) and neurofibromatosis 2 (NF2).

Neurofibromatosis 1 (NF1)

Definition: Autosomal-dominant disorder characterized by multiple neurofibromas, malignant peripheral nerve sheath tumor, optic nerve glioma, multiple café-au-lait spots, axillary and inguinal freckling, pigmented hamartomas of the iris (Lisch nodule), and various osseous lesions.

Synonyms: von Recklinghausen disease; peripheral neurofibromatosis

Clinical

- Most common type with incidence reported to be 1/2500 to 3000 live births and a prevalence of 1 per 4000
- Autosomal dominant:
 - Gene localized to chromosome 17q11.2 codes a protein called neurofibromin thought to function as a tumor suppressor by acting as a negative regulator of RAS signaling pathway
 - About 50% of NF1 cases are caused by new (spontaneous) germline mutations, which with few exceptions occur in the paternal germline.
- No gender predilection; 40% of patients have the onset of disease before the first year of life, and onset of disease is uncommon after 25 years of age.
- Severity of disease varies from patient to patient and from family to family.
- Diagnostic criteria are detailed in [Box 13-4](#).
- Café-au-lait spots are often the first sign of disease:
 - Appear in newborns
 - Number and size increase during infancy.
 - May remain stable or regress in adults
- Pigmented hamartomas of the iris also referred to as Lisch nodules represent small, elevated clumps of pigment that appear on the surface of the iris (colored part of the eye)
 - Usually appear at around 6 to 10 years of age
 - Cause no vision problems
- Head and neck manifestations seen in up to approximately 35% of patients:

BOX 13-4 Neurofibromatosis 1: Diagnostic Criteria

Two or more of the following criteria are diagnostic for NF1:

- Six or more café-au-lait spots:
 - Greater than 5 mm in diameter in prepubertal patients
 - Greater than 15 mm in diameter in postpubertal patients
- Two or more neurofibromas of any type or one plexiform neurofibroma
- Axillary and/or inguinal freckling
- Optic nerve glioma
- A distinctive osseous lesion such as dysplasia of the sphenoid wing, thinning of long bone cortex with or without pseudoarthritis
- A first-degree relative (e.g., parent, sibling, or offspring) with NF1 according to the above criteria

- Peripheral nerve sheath tumors are slow-growing, found in virtually any location with the most common head and neck sites, including:
 - Skin, subcutaneous tissues, and soft tissues of the neck
 - Oral cavity affected in approximately 5% of cases and may include involvement of the lips, buccal mucosa, gingiva, and floor of mouth
- Accelerated growth noted during pregnancy and at puberty
- Sudden increase in size raises concern for possible malignant transformation
- Gliomas:
 - Majority are pilocytic astrocytomas within the optic nerve
 - Other gliomas in NF1 include diffuse astrocytoma and glioblastoma.
- NF1 patients are at increased risk of developing other tumors, including:
 - Malignant peripheral nerve sheath tumor (MPNST); see later
 - Pheochromocytoma
 - Duodenal carcinoid tumor
 - Rhabdomyosarcoma
 - Childhood chronic myeloid leukemia (often associated with cutaneous xanthogranulomas)
- Osseous lesions occur in approximately 40% of NF1 patients and may include:
 - Sphenoid wing dysplasia
 - Scoliosis
 - Height reduction
 - Macrocephaly
 - Pseudoarthritis usually of long bones, especially the tibia
- Vascular lesions include fibromuscular hyperplasia of renal artery and other arteries
- Genetics:
 - Associated with deletions, insertions, or mutations of *NF1* gene
 - *NF1* gene is a tumor suppressor gene located in the pericentromeric region of chromosome 17
 - *NF1* gene encodes a cytoplasmic protein known as neurofibromin ubiquitously distributed in all tissues but highest levels found in central and peripheral nervous system and in the adrenal gland

Pathology

- Neurofibromas include plexiform, diffuse, and dermal types.
- Malignant transformation of neurofibroma may occur:
 - Include rhabdomyoblastic or other heterologous elements (Triton tumors):
 - Highly characteristic of NF1

- May include the glandular variant of malignant peripheral nerve sheath tumor:
 - Another lesion indicative of NF1

Treatment and Prognosis

- There are no treatment modalities that alter the course of NF1.
- Management depends on specific manifestations and often requires multidisciplinary collaboration.
- Complete surgical excision relative to the neurofibromas is problematic given their increased numbers as well as the tendency to infiltrative and ill-defined growth.
- Surgery is indicated for:
 - Tumors located in areas where compromise of function or involvement of vital structures may occur
 - Large tumors
 - Painful tumors
 - For cosmetic deformities
 - Tumors that have become malignant
- Optic gliomas that affect vision can be treated with surgery and/or radiation.
- Most serious complication is malignant transformation of a peripheral nerve sheath tumor:
 - Lifetime risk of NF1 patients developing malignant peripheral nerve sheath tumor is 5% to 10%
 - Usually occurs at a younger age
 - Usually seen in long-standing, deep-seated, large central, plexiform-type neurofibroma
 - Presents with a rapidly enlarging or painful (pre-existing) lesion
 - Should always be biopsied
 - Requires radical excision or amputation
 - May benefit from radiotherapy
 - Associated with a poor prognosis with <20% 5-year survival rates

Neurofibromatosis 2 (NF2)

Definition: Autosomal-dominant disorder characterized by neoplastic or dysplastic lesions of Schwann cells, meningeal cells, and glial cells; bilateral vestibular (acoustic) schwannomas are diagnostic.

Synonyms: Central neurofibromatosis; bilateral acoustic neurofibromatosis

Clinical

- Less common type with incidence reported to be 1/25,000 to 40,000 live births
- Autosomal dominant with a high rate of penetrance (95%); gene localized to chromosome 22q12.2:
 - About 50% of NF2 cases are caused by new (spontaneous or de novo) germline mutations
- No gender predilection; affects young patients with a mean age of presentation of 28 years of age

BOX 13-5 Neurofibromatosis 2: Diagnostic Criteria

The following criteria are diagnostic for NF2:

- Bilateral vestibular schwannomas
 - A first-degree relative (e.g., parent, sibling, or offspring) with NF2, and either
 - A vestibular schwannoma or
 - Two of the following: meningioma, schwannoma, glioma, posterior subcapsular lens opacity, or cerebral calcification or
 - Two of the following:
 - Unilateral vestibular schwannoma
 - Multiple meningiomas
 - Either schwannoma, glioma, neurofibroma, posterior subcapsular lens opacity, or cerebral calcification
- Diagnostic criteria are detailed in [Box 13-5](#).
 - Schwann cell tumors/lesions in NF2 include:
 - Schwannoma and schwannomatosis
 - Hallmark of NF2 is bilateral vestibular (acoustic) neuromas:
 - Seen in more than 90% of patients with NF2
 - Accounts for approximately 5% of all vestibular neuromas
 - Symptoms usually occur in teenage years or early third decade of life
 - Symptoms include:
 - Early: hearing (sensorineural) loss, tinnitus, dizziness
 - Late: headache, facial pain and/or weakness, others
 - Both tumors may not occur at the same time; therefore occurrence of an acoustic neuroma in a patient under 30 years of age should raise suspicion for a possible diagnosis of NF2.
 - Occasionally, unilateral vestibular (acoustic) neuroma may occur in patients with NF2 in the absence of other criteria necessary for a diagnosis of NF2.
 - Approximately 50% to 67% of patients with NF2 develop cutaneous schwannomas.
 - Schwannomatosis (multiple schwannomas):
 - Distinct clinicopathologic entity representing a third major form of neurofibromatosis that causes multiple schwannomas without vestibular tumors diagnostic of NF2:
 - Previously but no longer considered an attenuated form of NF2
 - Represent 2.4% to 5% of all patients requiring schwannoma resection
 - Approximately one third of patients with schwannomatosis have anatomically localized disease with tumors limited to a single limb or segment of spine
 - Epidemiologic studies suggest that schwannomatosis is as common as NF2, but that familial occurrence is inexplicably rare.

- NF2 loss in schwannomatosis is not germline:
 - Detectable in tumors
 - Differs among various lesions in any one patient and in tumors from other affected family members
 - Lineage studies of schwannomatosis kindreds place the schwannomatosis locus centromeric to *NF2* on chromosome 22q.
 - Mutation analysis of normal and tumor tissues in familial schwannomatosis found germline mutations of *SMARCB1/INI1* gene; mutations of *SMARCB1/INI1* not typically found in schwannomatosis; tumorigenesis is thought to occur through a four-hit, three-step model, beginning with a germline mutation in *SMARCB1* (hit 1), followed by loss of a portion of chromosome 22 that contains the second *SMARCB1* allele and one *NF2* allele (hits 2 and 3), followed by mutation of the remaining wild-type *NF2* allele (hit 4); expression of *SMARCB1* protein in a proportion of cells from schwannomatosis-related schwannomas suggests that these tumors develop through a mechanism that is distinct from that of rhabdoid tumors in which *SMARCB1* protein is completely absent in tumor cells.
- More common in men than women
- Schwannomas tend to be painful, involve skin and subcutaneous tissues, and may be segmental in distribution
- Schwannomas are of peripheral nerves, cranial nerves, or spinal nerves, but there is no development of the central nervous system neoplasms seen in association with NF2.
- Molecular genetic analysis shows the presence of somatic (in the tumor) but not germline (in all tissues) mutations.
- Pain remains the primary clinical problem and indication for surgery.
- Diagnostic criteria are detailed in Boxes 13-6 and 13-7.
- Meningeal tumors/lesions in NF2 include:
 - Meningiomas and meningioangiomas
 - Multiple meningiomas represent the second hallmark of NF2.
 - Occur earlier in life than sporadic meningioma
 - Meningioangiomas:
 - Cortical lesion characterized by a single, intracortical lesion
 - May be multifocal as well as noncortical
 - May be predominantly vascular or predominantly meningothelial
 - May be associated with a meningioma

BOX 13-6 Schwannomatosis: Diagnostic Criteria**Definite**

- Age >30 years
AND
- 2 or more nondermal schwannomas (at least one with histologic confirmation)
AND
- No MRI evidence of vestibular schwannoma
AND
- No known *NF2* germline mutation
OR
- One histologically proven peripheral (nonvestibular) schwannoma plus first-degree relative meeting above criteria

Possible

- Age <30 years
AND
- 2 or more nondermal schwannomas (at least one with histologic confirmation)
AND
- No MRI evidence of vestibular schwannoma
AND
- No known *NF2* germline mutation
OR
- Age <45 years
AND
- 2 or more nondermal schwannomas (at least one with histologic confirmation)
AND
- No symptoms of eighth nerve dysfunction
AND
- No known *NF2* germline mutation

Data from MacCollin M et al: *Neurology* 64:1838-1845, 2005;
Plotkin SR et al: *Am J Med Genet A* 161A:405-416, 2013.

- In association with NF2 may be multifocal and often asymptomatic; diagnosed at autopsy
- Sporadically occurring, usually single lesion in children or young adults presenting with seizures of persistent headaches
- Glial tumors/lesions in NF2 include:
 - Gliomas and glial microhamartomas
 - Approximately 80% are spinal intramedullary or cauda equina tumors, and 10% occur in the medulla.
 - Ependymomas account for approximately 65% to 75% of all gliomas in NF2 and for almost all spinal gliomas, in which they tend to be multiple intramedullary masses.
 - Diffuse and pilocytic astrocytomas occur in NF2 but are less common.
 - Glial microhamartomas:
 - Cerebral cortical lesions
 - Common in and pathognomonic of NF2
 - Not associated with mental retardation or astrocytomas
- Other findings include cerebral calcifications and peripheral neuropathy:

BOX 13-7 Schwannomatosis: New Proposed Diagnostic Criteria

Diagnostic criteria proposed by MacCollin et al predated the ability to perform molecular testing for schwannomatosis and did not take account of the possibility of multiple meningiomas as a presenting feature. Based on these findings, Plotkin et al propose the following new criteria for diagnosis of schwannomatosis:

Molecular Diagnostic Criteria

- Two or more pathologically proved schwannomas or meningiomas
AND
- Genetic studies of at least two tumors with loss of heterozygosity (LOH) for chromosome 22 and two different *NF2* mutations; if there is a common *SMARCB1* mutation, this defines *SMARCB1*-associated schwannomatosis
- One pathologically proved schwannoma or meningioma

Clinical Diagnosis

- Two or more nonintradermal schwannomas, one with pathologic confirmation, including no bilateral vestibular schwannoma by high-quality MRI (detailed study of internal auditory canal with slices no more than 3 mm thick). Recognize that some mosaic NF2 patients will be included in this diagnosis at a young age and that some schwannomatosis patients have been reported to have unilateral vestibular schwannomas or multiple meningiomas
- One pathologically confirmed schwannoma or intracranial meningioma AND affected first-degree relative
- Consider as possible diagnosis if there are two or more nonintradermal tumors but none has been pathologically proven to be a schwannoma; the occurrence of chronic pain in association with the tumor(s) increases the likelihood of schwannomatosis

Patients with the following characteristics do not fulfill the diagnosis for schwannomatosis:

- Germline pathogenic *NF2* mutation
- Diagnostic criteria for NF2
- First-degree relative with NF2
- Schwannomas in previous field of radiation therapy only

Data from MacCollin M et al: *Neurology* 64:1838-1845, 2005;
Plotkin SR et al: *Am J Med Genet A* 161A:405-416, 2013.

- Intracranial calcifications noted on neuroimaging in NF2
 - Preferred localization includes:
 - Cerebral and cerebellar cortices, periventricular areas, and choroid plexus
- Some NF2 patients develop sensorimotor peripheral neuropathy secondary to focal schwannomatous changes or perineurial cell proliferation.
- Extraneural manifestations include:
 - Posterior lens opacities:
 - Common and highly characteristic of NF2
 - Retinal hamartomas
- Café-au-lait spots and neurofibromas are rare in NF2.
- Cytogenetics and molecular biology:

- *NF2* gene is a tumor suppressor gene located on chromosome 22q12.2.
- *NF2* gene is expressed in most normal human tissues including brain.
- *NF2* gene encodes the protein merlin or schwannomin member of the moesin-ezrin-radixin cytoskeleton-associated proteins expressed in:
 - Schwann cells
 - Meningeal cells
 - Lens of the eye
- Most cases of NF2 are associated with absence of the gene product merlin
- A small but significant number of cases of NF2 and sporadic schwannomas either have no NF2 inactivation or have inactivation of only one allele.

Pathology

- Schwannomas:
 - Histologically identical to sporadic-occurring schwannomas
 - Are usually WHO grade I
 - In relation to the vestibular nerve, may entrap facial nerve fibers and have higher proliferative activity
- Meningiomas:
 - All types occur in NF2.
 - Are usually WHO grade I
 - Atypical or malignant meningiomas are not increased in NF2.

Treatment and Prognosis

- Surgery is indicated for many of the tumors associated with NF2 and should be directed at excising the tumor while preserving functional integrity of the affected site.
- Clinical course varies widely between families and within families.

BENIGN MYOGENIC TUMORS

- Benign myogenic tumors of the neck are uncommon and include tumors of smooth muscle differentiation (leiomyomas) and skeletal muscle differentiation (rhabdomyomas).
- Leiomyomas are benign mesenchymal tumors with smooth muscle differentiation.
- For a more complete discussion of smooth muscle neoplasms see Section 1, Chapter 4, Sinonasal Tract.

Rhabdomyoma

Definition: Benign mesenchymal tumor with skeletal muscle differentiation.

- Rhabdomyomas can be classified as cardiac or extra-cardiac and by histology; the histologic classification includes:
 - Adult
 - Fetal
 - Juvenile

NOTE: The separation of adult-type from fetal-type and juvenile-type rhabdomyomas is based on their histologic appearance rather than the age of the patient.

Adult-Type Rhabdomyoma

(Fig. 13-27)

Clinical

- More than 90% occur in the head and neck.
- Considerably less common than their malignant counterparts (rhabdomyosarcoma)
- Much more common in men than in women; may occur over a wide age range but tends to occur in older population than fetal type, usually in adults over 40 years of age
- Predilection for the head and neck:
 - The most commonly affected site is the neck.
 - Other sites of occurrence include the oral cavity (base of tongue and floor of mouth), oropharynx, and larynx.
- Majority are solitary; up to 20% may be multifocal, synchronous, or dyssynchronous.
- Symptoms vary according to site and include painless neck mass, dysphagia, dyspnea, and hoarseness.
- No association with tuberous sclerosis (unlike cardiac rhabdomyomas, which are associated with tuberous sclerosis)

Fig. 13-27. Adult-type rhabdomyoma of the lateral neck.

A, Circumscribed, multinodular, red-brown mass. **B,** Low-power view of adult rhabdomyoma characterized by admixture of deeply eosinophilic polygonal cells with small peripherally placed nuclei and cells with vacuolated cytoplasm. **C,** At higher magnification cells have a finely granular-appearing cytoplasm. **D,** The identification of cross-striations may be aided by staining with phosphotungstic acid-hematoxylin (PTAH).

Pathology

Gross

- Well-delineated or circumscribed, (multi)lobulated, red-brown mass ranging in size from 0.5 to 6.0 cm in greatest dimension; larger tumors may occur

Histology

- Sheet-like proliferation of tightly packed large, polygonal to round cells with abundant deeply eosinophilic, granular cytoplasm and one or two peripherally placed vesicular nuclei; prominent nucleoli occasionally may be prominently identified:
 - Many cells show prominent cytoplasmic vacuolization due to intracytoplasmic glycogen accumulation.
 - Some cells are elongated cells showing similar nuclear and cytoplasmic features may be present.
 - Some cells have a small central acidophilic cytoplasmic mass connected by thin strands of cytoplasm to a condensed rim of cytoplasm at the periphery so-called spider cells, which are more prevalent in cardiac rhabdomyomas than extra-cardiac rhabdomyomas
 - Intracytoplasmic cross-striations may be identifiable.
- Cross-striations are usually readily identifiable; intracytoplasmic rod-like (jackstraw-like) crystalline structures may also be readily identifiable.
- Mitoses and necrosis are absent.
- Histochemistry:
 - Contain abundant cytoplasmic glycogen as seen by the presence of intracytoplasmic diastase-sensitive, PAS-positive material
 - Phosphotungstic acid-hematoxylin (PTAH) stain cross-striations and crystalline structures
- Immunohistochemistry:
 - Immunoreactive for muscle-specific actin, desmin, and myoglobin
 - Variably immunoreactive for vimentin, S100 protein, and smooth muscle actin
 - No immunoreactivity for cytokeratins, EMA, chromogranin, synaptophysin, glial fibrillary acidic protein, or CD68
- Electron microscopy:
 - Haphazard arrangement of intracytoplasmic thin and thick myofilaments with varying degree of differentiation measuring 50 to 70 nm
 - Distinct Z lines are identified within the I band
 - Cells are surrounded by basal lamina with focal infoldings of the plasma membrane.
 - Variable number of mitochondria and glycogen
 - Absence of cell junctions
- Cytogenetics and molecular genetics:
 - Reciprocal translocation of chromosomes 15 and 17

Fig. 13-28. Crystal storing histiocytosis.

A, Cells simulate those seen in rhabdomyoma due to intracellular immunoglobulin crystal deposition. **B**, Cells are immunoreactive for CD68 (KP1).

- Abnormalities in long arm of chromosome 10
 - Above findings lend support to the neoplastic (rather than hamartomatous) nature of rhabdomyomas

Differential Diagnosis

- Granular cell tumor
- Alveolar soft part sarcoma
- Hibernoma
- Paraganglioma
- Crystal storing histiocytosis (Fig. 13-28):
 - Intracellular immunoglobulin crystal deposition in histiocytes is rare and can be seen in association with lymphoplasmacytic or plasma cell neoplasms.
 - Represents a dysproteinemia-associated lymphoproliferative process
 - Occurs in soft tissues particularly in the head and neck region, as well as the lung and other sites

- Light microscopic features simulate the cells seen in rhabdomyoma
- Crystal-containing cells are positive for CD68 (KP-1), but negative for desmin, muscle-specific actin, or myoglobin.
- Ultrastructural findings of the crystalline material show a lattice pattern with periodicity of 45 to 60Å the crystalline material consistent with immunoglobulin

Treatment and Prognosis

- Complete surgical excision is curative.
- May recur if incompletely excised

Rhabdomyoma, Fetal and Juvenile-Intermediate Types

Definition: Tumors showing spectrum of skeletal muscle differentiation ranging from immature, predominantly myxoid tumors (fetal type) to tumors showing a high degree of cellular differentiation with limited to absent myxoid matrix (intermediate type).

Rhabdomyoma, Fetal Type

(Fig. 13-29)

Synonym: Fetal rhabdomyoma, myxoid type

Clinical

- Rare tumor
- Much more common in males than females; most common in patients under 3 years of age; rare in adults
- Most common sites of occurrence include postauricular and preauricular subcutaneous tissues; less common sites of occurrence include the nasopharynx, parotid gland, and neck.
- Symptoms vary according to site:
 - Postauricular region presents as a slow-growing, painless mass.
- Usually solitary but may be multifocal:
 - Multifocal tumors reported in association with nevoid basal cell carcinoma syndrome:
 - Autosomal-dominant disorder
 - Characterized by multiple basal cell carcinomas occurring early during childhood, various skeletal abnormalities, and odontogenic keratocyst
 - Mutations in PTCH tumor suppressor gene implicated in development of this syndrome

Pathology

Gross

- Solitary, well to moderately circumscribed nodule measuring from 1 to 8 cm with a gray to pink, mucoid, glistening appearance

Fig. 13-29. Fetal rhabdomyoma.

A, The tumor comprises an admixture of primitive round and spindle-shaped cells and differentiated myofibrils arranged in short fascicles within a myxoid stroma. **B,** At higher magnification the myofibrils show little variation in size or shape of the muscle cells with absent mitoses, which would contrast to the features seen in association with rhabdomyosarcoma. Tumor cells are immunoreactive for desmin, muscle-specific actin, and myoglobin (not shown).

- Mucosal-based lesions are smooth with a polypoid or pedunculated appearance.

Histology

- Superficially located rather than deeply situated within muscle
- Cellularity varies to include sparse to moderately cellular (myxoid) and cellular types.
- Primarily composed of primitive undifferentiated oval to spindle-shaped cells with indistinct cytoplasm; interspersed immature skeletal muscle fibers within a copious myxoid stroma are identified:

- Immature cells have uniform small, round to oval to spindle-shaped nuclei, inconspicuous to identifiable nucleoli, scanty indistinct cytoplasm and bipolar and multipolar eosinophilic cytoplasmic processes
- Cell arrangement may include short bundles or be isolated in the myxoid stroma
- Strap cells with cross-striations rarely discernible
- Occasionally, large round cells with eosinophilic cytoplasm similar to those seen in adult rhabdomyoma may be identified.
- Nuclear atypia is not present; mitoses and necrosis are typically absent; in limited examples both may be present, but atypical mitoses are not identified.
- Rarely, intimate association with peripheral nerves may be present:
 - Referred to as neural variant of fetal rhabdomyoma
 - Similar to and must be differentiated from neuromuscular choristoma (benign Triton tumor)
- Histochemistry:
 - Masson trichrome and phosphotungstic acid-hematoxylin (PTAH) assist in the possible identification of cross-striations.
- Immunohistochemistry:
 - Desmin, muscle-specific actin, and myoglobin positive
 - Variable (and often limited to absent) reactivity for smooth muscle actin, S100 protein, and vimentin
 - Glial fibrillary acidic protein (GFAP), keratin, EMA, and CD68 negative
- Electron microscopy:
 - Organized bundles of myofilaments (thick myosin and thin actin) with characteristic banding in differentiated muscle cells
 - Rod-like cytoplasmic inclusions and hypertrophied Z-band material may be identified but are less common as compared with adult rhabdomyoma
 - Intracellular glycogen
 - Spindle cells lack cellular differentiation
- Cytogenetics and molecular genetics:
 - Aberrations at PTCH1 locus including PTCH1 frameshift mutation and homozygous deletions of PTCH1 suggest that activated Hedgehog signaling contributes to the biology of fetal rhabdomyomas.

Differential Diagnosis

- Rhabdomyosarcoma, embryonal and spindle cell types:
 - Presence of nuclear atypia and mitotic figures, including atypical mitoses as well as necrosis and

infiltrative growth, assists in differentiating fetal rhabdomyoma from rhabdomyosarcoma.

- Utility of myogenin and MyoD1 in differentiating from rhabdomyoma remains uncertain

Treatment and Prognosis

- Conservative but complete surgical resection is curative.

Rhabdomyoma, Juvenile-Intermediate Type (Fig. 13-30)

Clinical

- Rare tumor
- More common in men than in women; affects older ages as compared with fetal (myxoid)-type rhabdomyoma, affecting adolescents (usually older than 15 years of age) and adults
- Predilects to the head and neck region with common sites of occurrence, including:
 - Orbit, tongue, nasopharynx, and soft palate
- Symptoms vary according to site but usually is that of a slow-growing, painless mass.
- Some consideration has been given to fetal-type and juvenile-type rhabdomyomas representing a hamartoma or congenital anomaly rather than a true neoplasm; however, support of the neoplastic nature of these lesions includes:

Fig. 13-30. Rhabdomyoma, juvenile-intermediate type.

Cellular tumor characterized by the presence of cells showing skeletal muscle differentiation, including strap-shaped muscle cells and ganglion-like cells with large vesicular nuclei and prominent nucleoli. Tumor cells are immunoreactive for desmin, muscle-specific actin, and myoglobin (not shown).

- Association with nevoid basal cell carcinoma syndrome:
 - Autosomal-dominant disorder
 - Characterized by multiple basal cell carcinomas occurring early during childhood, various skeletal abnormalities, and odontogenic keratocyst
 - Mutations in PTCH tumor suppressor gene implicated in development of this syndrome

Pathology

Gross

- Similar to fetal-type rhabdomyoma

Histology

- Superficially located rather than deeply situated within muscle
- Characterized by the presence of numerous cells showing skeletal muscle differentiation:
 - Predominant cell is strap-shaped muscle cell with abundant eosinophilic cytoplasm and centrally located vesicular nuclei; cells with cross-striations are frequently identified.
 - Cells with rhabdomyoblastic maturation, including prominent ganglion-like cells with large vesicular nuclei and prominent nucleoli, are present.
 - Cells with vacuolated cytoplasm due to increased glycogen can be seen.
 - Typically there is little to absent myxoid stroma.
- Transitional areas showing a coexisting intermediate-type and fetal (myxoid)-type rhabdomyoma are not infrequently identified.
- Nuclear atypia, increased mitotic activity, and necrosis are typically absent; in limited examples both may be present, but atypical mitoses are not identified.
- Rarely, intimate association with peripheral nerves similar to neuromuscular choristoma may be present.
- Histochemistry:
 - Intracytoplasmic diastase-sensitive, PAS-positive material indicative of glycogen is present.
 - Masson trichrome and phosphotungstic acid-hematoxylin (PTAH) assist in the possible identification of cross-striations.
- Immunohistochemistry:
 - Desmin, muscle-specific actin, and myoglobin positive
 - May be positive for SMA, S100 protein, vimentin
 - Cytokeratin, EMA, and CD68 negative
- Electron microscopy:
 - Organized bundles of myofilaments (thick myosin and thin actin) with characteristic banding in differentiated muscle cells
 - Rod-like cytoplasmic inclusions and hypertrophied Z-band material may be identified but

are less common as compared with adult rhabdomyoma

- Intracellular glycogen
- Spindle cells lack cellular differentiation.

Differential Diagnosis

- Rhabdomyosarcoma, embryonal, and spindle cell types:
 - Presence of nuclear atypia and mitotic figures, including atypical mitoses, assists in differentiating fetal rhabdomyoma from rhabdomyosarcoma.
 - Utility of myogenin and MyoD1 in differentiating from rhabdomyoma remains uncertain

Treatment and Prognosis

- Conservative but complete surgical resection is curative.

TERATOMATOUS NEOPLASMS

Teratoma (Fig. 13-31)

Definition: Tumor composed of a variety of mature tissues derived from two or three germ layers and foreign to the site of occurrence.

Clinical

- In the head and neck rare neoplasms accounting for less than 2% of all teratomas.
- No gender predilection; majority occurs in newborns or infants and is rarely seen over the age of 1 year (cervical teratoma) and 2 years (nasopharyngeal teratoma):
 - Most tumors in neonates are benign.
 - May be seen in the adult population
 - More than 50% of tumors in adults are malignant.
- Most common locations in the head and neck include:
 - Neck and nasopharynx
 - Other less commonly involved sites include oral cavity (tonsil, tongue, palate), sinonasal cavity, external and middle ear and temporal bone, mandible and maxilla, and thyroid gland.
- Presenting symptoms include:
 - Cervical teratoma: neck mass that may compress the trachea, resulting in airway obstruction (stridor, apnea)
 - Nasopharyngeal teratoma: mass protruding into the oral cavity or pharynx causing associated dysphagia and/or airway obstruction
- May present prenatally with signs and symptoms, including:
 - Polyhydramnios, fetal hydrops, and identification of mass by fetal ultrasound

Fig. 13-31. Cervical neck mature teratoma.

A, Large mass that clinically compressed the trachea, resulting in airway obstruction. **B**, Cut section showing predominantly solid tissue with a tan-brown to fleshy appearance. **C**, Histologic composition of teratomas includes elements from all germ cell layers, including epithelial (squamous and columnar), mesenchymal structures (cartilage), and central nervous system tissue. **D**, *Left*, epithelial lined glands and immature cartilage; *right*, central nervous system tissue.

- May be associated with maternal hydramnios and stillbirth
- In contrast to teratomas occurring in the pediatric population, teratomas of the head and neck in adults:
 - Occur much less frequently
 - Tendency for a larger percentage of these tumors to be malignant
- Derivation thought to be from primordial germ cells or primitive somatic cells

Pathology

Gross

- Encapsulated cystic, solid, or multiloculated mass measuring in size from 5 to 17 cm in diameter

Histology

- Composition includes the identification of tissue arising from all three germ layers, including:
 - Epithelial: keratinizing squamous, columnar, ciliated respiratory or gastrointestinal-type epithelium, cutaneous adnexa, minor salivary glands; thyroid parenchyma may be found in a minority of cases
 - Neuroectodermal and central nervous system tissue:
 - Particularly in nasopharyngeal and sinonasal teratomas, neuroectodermal and neural tissue components predominate.

- May include mature glial tissue, neurofibrillary matrix, neural rosettes, and/or choroid plexus
- Mesenchymal: cartilage, bone, fat, and smooth muscle
- Epithelial-lined cystic spaces are prominent.
- Immature or embryonal tissue components can be identified throughout the tumor.
- Necrosis and hemorrhage may be seen.
- Grading:
 - Completely mature tumors: grade 0
 - Predominantly mature: grades 1 and 2
 - Mostly immature: grade 3 or malignant
- Malignant teratoma and germ cell tumors (Fig. 13-32):
 - Rare tumors in the head and neck
 - No gender predilection; occur over a wide age range from the third through the eighth decades of life
- Malignant teratoma:
 - Histologic evaluation demonstrates a prominent neural component associated with poorly differentiated carcinoma and/or sarcoma.
 - In the adult setting, increased cellular immaturity has prognostic significance as demonstrated by a greater malignant potential; additionally, adult teratomas with benign histology may recur or metastasize.
 - Metastases commonly occur via lymphatic and vascular routes.
 - Aggressive therapy is indicated.
- Prognosis is poor.
- Germ cell tumors:
 - Yolk sac tumor (endodermal sinus tumor)
 - Rare in the head and neck
 - May occur in association with immature teratoma or independent of a teratoma as exclusive histopathologic element

Fig. 13-32. Cervical neck immature (malignant) teratoma.

A, Immature neural-type tissue with neural rosettes. **B**, Synaptophysin reactivity in the immature neural tissue infiltrate. **C**, Cohesive clusters of undifferentiated malignant cells. **D**, Cytokeratin reactivity confirms the epithelial nature (i.e., carcinoma) of the undifferentiated malignant cells.

- Rare reports include occurrence in association with sinonasal nonkeratinizing carcinoma.
- Majority of patients are children under 1 year of age.
- Sites of occurrence may include oral cavity, nasopharynx and/or sinonasal tract, oropharynx, ear, salivary glands.
- Associated with elevated serum alpha-fetoprotein (AFP)
- Histology identical to gonadal yolk sac tumors including:
 - Intermingling of epithelial and mesenchymal elements in organoid manner
 - Growth patterns include reticular (microcystic, vacuolated), macrocystic, papillary, solid, glandular/alveolar, endodermal sinus (perivascular, festoon), myxomatous, hepatoid, sarcomatoid, polyvesicular vitelline
 - Perivascular Schiller-Duval bodies (glomeruloid bodies) represent most distinctive feature, characterized by papillary core of fibrous tissue with central small blood vessel ringed by layer of malignant-appearing cuboidal to columnar cells
 - Hyaline globules (intracytoplasmic) consistently present: not specific for yolk sac tumor; tend to occur in clusters iastase-resistant, PAS positive
 - Immunohistochemical reactivity includes: alpha-fetoprotein (AFP) positive (cytoplasmic staining); pancytokeratin and SALL4 (nuclear) positive; glypican 3 positive (cytoplasmic and membranous); CK7 typically negative; OCT3/4 negative; hyaline globules usually AFP negative but may be positive
 - May rarely occur in association with choriocarcinoma
- Aggressive tumor requiring equally aggressive management including
 - Complete surgical excision is recommended, although this may not be possible.
 - Combination radiation and chemotherapy; use of platinum-based chemotherapy has improved survival
 - Often metastasizes to lymph nodes and viscera (e.g., bone, lungs, liver, others)
 - Serum AFP level can be used to monitor response to treatment as well as in detecting tumor recurrence
- Choriocarcinoma:
 - Rarely occurs outside the genital tract
 - Occurrence in the head and neck is rare and presence in head and neck should prompt exclusion of metastasis from genital tract.
 - To date, identification limited to sinonasal tract
 - Associated with elevated serum beta-human chorionic gonadotropin (HCG) levels
 - Usually hemorrhagic and necrotic tumors
 - Histology includes:
 - Admixture of syncytiotrophoblast cells with large atypical nuclei with mononuclear trophoblast cells (cytotrophoblasts) creating biphasic pattern; syncytiotrophoblast cells show variable morphology but most often include large cells with hyperchromatic irregular nuclei and eosinophilic to amphophilic cytoplasm; distinct cytoplasmic vacuoles or lacunae are present, which may contain erythrocytes; cytotrophoblasts consist of mildly pleomorphic nuclei with prominent nucleoli and pale to clear cytoplasm; discrete cell borders usually present; syncytiotrophoblasts “cap” proliferating cytotrophoblast cells (villus-like pattern); more common to show random admixture of syncytiotrophoblast cells with cytotrophoblast cells; vascular invasion commonly seen
 - Immunohistochemical reactivity includes: presence of hCG in syncytiotrophoblasts and occasionally positive in cytotrophoblasts; syncytiotrophoblasts reactive for inhibin, epidermal growth factor, and glypican 3; cytokeratin reactivity in syncytiotrophoblasts and cytotrophoblasts; EMA positive mainly in syncytiotrophoblasts; p63 (nuclear) reactivity in cytotrophoblasts
 - Treatment includes chemotherapy for germ cell malignancy.
- Too few cases reported in the literature to suggest true outcome but may metastasize and prove lethal or respond to therapy with disease-free survival.

Differential Diagnosis

- Teratoid lesions (dermoid cysts, nasopharyngeal “hairy polyp”)
- Heterotopic central nervous system tissue or encephalocele
- Cystic hygroma

Treatment and Prognosis

- Complete surgical excision is the preferred treatment and is curative.
- Prenatally diagnosed cases can be delivered preterm by cesarean section with immediate intubation

and ventilation aim for respiratory stabilization followed by elective resection.

- Morbidity may be high due to the size and location of the tumors.
- Mortality rates are low if surgical intervention is initiated early; however, death may ensue if not adequately treated and is usually caused by complications of respiratory obstruction.
- Nasopharyngeal teratomas may extend intracranially.
- Lymph node metastases may be seen but may reflect “benign” metastases rather than an indication of malignancy.

- In the pediatric age group, malignant transformation or behavior of a head and neck teratoma has not been reported.
- Adult teratoid lesions of the head and neck should be considered to be malignant teratomas until proven otherwise.
- Finding of immature or embryonic tissue components is not of any prognostic significance.

MALIGNANT TUMORS OF THE NECK

HEMATOLYMPHOID MALIGNANT NEOPLASMS

General Considerations

- Malignant lymphomas are generally divided into two major categories: non-Hodgkin lymphoma and Hodgkin disease.
- The vast array of clinical and pathologic features of the malignant lymphoproliferative diseases are beyond the scope of this text.
- See sections on the sinonasal tract (Section 1) and pharynx (Section 3) for detailed discussion of site-specific lymphomas.
- Follicular dendritic cell sarcoma can arise in lymph nodes of the cervical neck or extranodal sites, in particular, the tonsils; see Section 3, Pharynx, for a more complete discussion.

SARCOMAS OF THE NECK

- In general, sarcomas of the neck are uncommon.
- Although uncommon, virtually all types of sarcomas may occur in these sites.

Malignant Peripheral Nerve Sheath Tumors (MPNST)

(Figs. 13-33 and 13-34)

Definition: Malignant neoplasm (sarcoma) arising from cells intrinsic to the nerve sheath or having differentiation along the lines of various elements of the nerve sheath.

- Diagnosis is predicated on:
 - Origin from a nerve (exclusive of perineurium) or preexisting benign nerve sheath tumor (usually neurofibroma but may also include schwannoma, ganglioneuroblastoma)

- Ultrastructural evidence of Schwann cell differentiation
- Development of a spindle cell sarcoma in patient with NF1 with histologic features of MPNST
- In the absence of the above findings, a diagnosis can be made based on histologic, immunohistochemical, and ultrastructural features of Schwann cell differentiation.

Synonyms: Malignant schwannoma; neurogenic sarcoma; neurofibrosarcoma

Clinical

- Uncommon tumor accounting for approximately 5% of all soft tissue sarcomas; most commonly occurs in the lower extremity
- Up to 20% may occur in the head and neck:
 - Most common site of involvement is the neck.
 - Less frequently, other sites of involvement include sinonasal tract, nasopharynx, and oral cavity.
- Symptoms include:
 - Neck:
 - Mass with associated pain, paresthesia, and weakness
 - Sinonasal tract, nasopharynx, oral cavity:
 - Mass lesion, pain, epistaxis, and nasal obstruction
- Occur in varying settings with different epidemiologic findings, including:
 - De novo (sporadic) MPNST
 - In the setting of neurofibromatosis 1 (NF1) characterized by loss of function mutations to the tumor suppressor neurofibromin
 - May also occur in areas previously irradiated

Sporadic or De Novo MPNST

- No gender predilection or slightly more common in women; occur over a wide age range but most frequent in the fifth decade
- No known cause

Fig. 13-33. Malignant peripheral nerve sheath tumor, low grade.

A, Infiltrating cellular tumor arranged in a fascicular growth with long sweeping ("herringbone-like") fascicles that swirl or interdigitate with one another. **B**, Neoplastic cells have elongated nuclei with an irregular contour and tapered ends when seen in profile and are asymmetrical oval when seen en face. **C**, Increased mitotic activity. **D**, S100 protein positive. Increased cellularity with nuclear pleomorphism and increased mitotic activity assist in differentiating low-grade malignant peripheral nerve sheath tumor from cellular schwannoma.

MPNST Associated with NF1

- Accounts for approximately 30% to 50% of all MPNSTs:
 - Lifetime risk in patients with NF1 is 5% to 10%
- No gender predilection or slightly more common in women; tends to occur in a younger age group (10 to 15 years younger) as compared with sporadic MPNST and is primarily seen in the third to fourth decades of life; can also occur in children
- Estimated risk of patients with NF1 developing MPNST varies from 4% to 50%
 - Occurrence typically follows a latent period of from 10 to 20 years
- MPNST not associated in patients with NF2 although rare example of MPNST spontaneously developing in patient with NF2 reported:
 - Rarity of development of MPNST in NF2 patients may be attributed to resistance of nonmelanotic schwannomas (which occur in NF2) to malignant transformation.

Radiation-Induced MPNST

- Approximately 10% are radiation-induced with post-treatment latency period usually greater than 10 years

Pathology

Gross

- Fusiform-shaped mass with a fleshy, tan-white appearance usually measuring more than 5 cm in diameter; attachment to a nerve may be identified.
- Cyst formation, hemorrhage, and necrosis are frequently present.

Histology

High-Grade MPNST

- Most MPNSTs are high grade and the following reflects those high-grade lesions; see later for a discussion on low-grade MPNST.
- Unencapsulated hypercellular proliferation composed of spindle-shaped cells:

Fig. 13-34. Malignant peripheral nerve sheath tumor, high grade.

A through **C**, Hypercellular neoplasm with less conspicuous fascicular growth as compared with its low-grade counterpart, but with increased cellularity, nuclear pleomorphism, hemorrhage, necrosis, and increased mitotic activity, including atypical forms. **D**, Focal S100 protein immunoreactivity.

- Cells have elongated nuclei with an irregular contour, tapered ends, and appearing wavy or buckled when seen in profile and asymmetrically oval when seen en face; cytoplasm is indistinct
- Cells are arranged in a fascicular growth with long, sweeping (“herringbone-like”) fascicles that swirl or interdigitate with one another.
- Perivascular accentuation or whorling of lesional cells that sometimes may include infiltration of lesional cells into vessel walls
- Abrupt alternation between cellular and hypocellular, myxoid areas
- Less common growth patterns may include nodules or whorled arrangement of neoplastic cells.
- Nuclei tend to be hyperchromatic and pleomorphic with inconspicuous nucleoli.
- Mitoses generally readily identifiable:
 - Most cases show at least four mitotic figures per 10 high-power fields.
 - Mitotic counts of 10 to 20 per 10 high-power fields are common.
- Necrosis can be found, including geographic type; tendency to spare lesional cells surrounding blood vessels (peritheliomatous pattern)
- In approximately 10% of cases abundant myxoid stroma may be present (myxoid MPNST)
 - Hypocellular areas with a myxoid stroma can be seen alternating with areas of greater cellularity.
- Nuclear palisading may be seen but typically is present in a minority of cases (less than 10%) and when present tends to be focally identified within a given tumor:
 - Nuclear palisading more common in other sarcomas (e.g., leiomyosarcoma, synovial sarcoma)
- Other findings seen include:
 - Presence of hyaline bands and nodules resembling giant rosettes when seen in cross-section
 - Perineural and intraneural spread of tumor
 - Proliferation of tumor in subendothelial zones of blood vessels given the appearance of tumor cells herniating into the lumen

- Heterologous elements can be identified in up to 10% to 15% of cases, especially those arising in NF1 patients:
 - Tend to be more commonly seen in association with MPNST than other sarcomas
 - Most commonly includes rhabdomyosarcomatous elements (malignant Triton tumor; see later)
 - Frequently includes osteosarcomatous or chondrosarcomatous differentiation
 - Angiosarcomatous differentiation rare
- Diagnosis of MPNST assisted by finding nerve fascicle(s) overrun by plexiform neurofibroma with or without perineurium involvement or a symmetrically expanded nerve infiltrated by tumor
- Invasion into soft tissue, lymph-vascular invasion, and osseous invasion may be seen.
- Immunohistochemistry:
 - S100 protein reactivity:
 - Represents most widely used marker in the diagnosis of MPNST
 - Low-grade MPNSTs consistent S100 protein positive while high-grade MPNSTs are variably positive
 - Variable reactivity reported, including from 50% to 90% of cases to 30% to 67% of cases:
 - Absence of S100 protein does not exclude diagnosis.
 - Not a unique marker for MPNST and seen in a wide variety of neoplasms (benign and malignant)
 - Sox10, a transcription factor in neural crest development and differentiation of neural crest cells into melanocytic and schwannian lineage, reactive (nuclear staining) in MPNSTs with reports showing better sensitivity and specificity in the diagnosis of MPNST than S100 protein
 - Vimentin positive
 - GFAP reactivity in 20% to 30% of cases
 - Variable reactivity for Leu-7 (CD57)
 - p53 expression (nuclear) present in high proportion of cases
 - Immunohistochemical staining for the newly developed monoclonal antibody binding to the C-terminus of neurofibromin (NFC) revealed loss of neurofibromin in 88% of NF1-associated 43% of sporadic MPNST.
 - Strong association of neurofibromin loss with deletions affecting the *NF1* gene
 - Limited loss of NFC in large series of other soft tissue tumors of different histotypes
 - Loss of neurofibromin not observed in synovial sarcomas, schwannomas, solitary fibrous tumors, low-grade fibromyxoid sarcomas, dedifferentiated liposarcomas, myxoid liposarcomas, angiosarcomas, extraskeletal myxoid chondrosarcomas, and epithelioid sarcomas
- Immunohistochemistry using antibody to NFC may substantially facilitate diagnosis and differential diagnosis of MPNST.
- Epithelial, neuroendocrine, melanocytic, and hematolymphoid markers typically negative:
 - EMA reactivity is rare and if present suggests perineurial differentiation.
- TLE1 negative
- p16 negative
- Cases with rhabdomyosarcomatous or angiosarcomatous differentiation stain for appropriate markers including desmin and myogenin for skeletal muscle differentiation and CD31, Factor 8, Fli-1, and ERG1 for endothelial differentiation.
- Electron microscopy:
 - Given relative lack of differentiation in high-grade MPNSTs, no more than approximately 50% show schwannian differentiation.
- Cytogenetics and molecular genetics:
 - No consistent karyotypic pattern
 - Complex and nonspecific karyotype abnormalities including chromosomal gains and losses
 - Often show *NF1* gene deletion or mutation:
 - Patients with NF1 carry germline alterations in *NF1* gene.
 - Biallelic mutations of *NF1*, whether occurring sporadically or in association with NF1
 - *TP53* gene mutations and alterations of protein expression are rare.
 - PTEN downregulation implicated in genesis of MPNSTs in NF1 (and in plexiform neurofibromas)
 - Homozygous deletions of *CDKN2A* gene:
 - Encodes two nonhomologous isoforms, *p14ARF* and *p16INK4a*
 - Both have important impact on cell-cycle progression;
 - Occurs in progression of neurofibromas to MPNST
 - Found in 50% of MPNST
 - Not present in neurofibromas
- Low-grade MPNST:
 - A minority of cases are low-grade and distinction from benign nerve sheath tumor with atypical features can be problematic
 - As compared with benign nerve sheath tumors, low-grade MPNSTs have:
 - Increased cellularity and increased mitotic activity; mitoses may be few in number but atypical mitoses are not typically present; necrosis is usually not present
 - May demonstrate infiltrative growth

- Histologic variants of MPNST include (all usually uncommon in the head and neck):
 - MPNST with rhabdomyosarcoma (malignant Triton tumor):
 - Approximately 60% associated with NF1
 - Rhabdomyoblasts are identified scattered throughout the tumor and their numbers vary from case to case:
 - Typically are mature in appearance with abundant eosinophilic cytoplasm
 - Cross-striations can be identified, especially in cells with elongated cytoplasm
 - Immunoreactive for desmin, myoglobin, and myf-4 (nuclear staining); actin reactivity may be present.
 - Glandular MPNST:
 - Rare variant
 - Almost all arise in patients with NF1
 - Contains gland formation:
 - Intestinal appearance most often are benign appearing, composed of well-differentiated, nonciliated cuboidal or columnar cells and clear cytoplasm; goblet cells may be present
 - Intracellular and intercellular mucin may be present.
 - Rarely, squamous differentiation may be present.
 - Immunoreactivity for cytokeratin, carcino-embryonic antigen, epithelial membrane antigen, and neuroendocrine markers
 - Rarely, glands are histologically malignant.
 - Epithelioid MPNST
 - Rare variant representing approximately 5% (or less) of cases
 - Not associated with NF1
 - Most common type to arise in association with a pre-existing benign schwannoma
 - Most are deep seated:
 - Lesions classified as superficial epithelioid MPNST likely represent benign epithelioid schwannoma or, less often, melanoma
 - Typically show lobulated growth
 - Predominantly or exclusively composed of cells with polygonal epithelioid appearance:
 - Large round nuclei with abundant eosinophilic cytoplasm
 - May include tumors with clear cells or rhabdoid cells
 - May be associated with abundant extracellular myxoid matrix with lobular growth
 - Immunohistochemistry:
 - Diffuse and intense S100 protein staining is present in a majority of cases.
 - Approximately 50% lack *SMARCB1* (INI1) immunostaining.

- Negative for melanocytic markers
- Approximately 50% of cases negative for INI1
- May be cytokeratin positive
- MPNST with perineurial differentiation (perineurial cell MPNST):
 - Seen in a very small percentage of cases
 - Perineurial component characterized by spindle cells with whorled or storiform growth pattern
 - EMA reactivity present rather than S100 protein

Differential Diagnosis

- Fibrosarcoma
- Leiomyosarcoma
- Synovial sarcoma, monophasic variant
- Malignant melanoma
- Benign tumors including:
 - Schwannoma, neurofibroma, soft tissue perineurioma

Treatment and Prognosis

- Complete surgical excision (gross total resection) is the preferred treatment:
 - Most are high-grade malignancies necessitating wide en bloc resection and postoperative radiotherapy
 - Chemotherapy is used for inoperable tumors and disseminated tumors.
- Local recurrence is common, reported in up to 50% of patients.
- Regional nodal metastases are uncommon (10% or less of patients) and as a result nodal neck dissection is generally not warranted.
- Distant metastases occur in approximately 33% of cases and most commonly spread to the lungs; less common metastatic sites include bone, pleura, and liver.
- Owing to the prevalence of higher-grade lesions, overall 5-year survival rate approximately 30% to 60%
- Survival of patients with NF1-associated MPNST previously believed to be lower than in patients with sporadic MPNST, but this is a controversial issue and likely not valid.
- Additional adverse prognostic findings include:
 - Larger tumor size (greater than 5 cm)
 - Location:
 - Truncal location slightly worse than extremity and head and neck
 - Resection with positive margin and (local) recurrence
 - Distant metastasis:
 - Increased risk of distant metastasis in large tumor, AJCC stage III, lack of S100

protein staining, and in patients requiring chemotherapy

- Radiation-induced sarcoma
- Malignant Triton tumors are particularly aggressive.

Additional Facts

- In the sinonasal cavity, MPNST can occur in the clinical setting of a sinonasal polyp:
 - Often low-grade and appears as a nondescript spindle cell proliferation in and around a benign glandular proliferation
 - S100 protein is invaluable in confirming the diagnosis
 - May in fact represent the low-grade sinonasal sarcoma with neural and myogenic features or biphenotypic sinonasal sarcoma (see Section 1, Sinonasal Tract)
- Pediatric MPNST:
 - MPNSTs are rare in childhood.
 - Associated with an unfavorable prognosis
 - Complete resection appears to be the most effective treatment.
 - Role of chemotherapy and/or radiotherapy remains uncertain.
 - Overexpressed survivin RNA reported to correlate with a higher tumor grade (grade 1 and 2 vs. grade 3) and with a lower survival probability, supporting the concept that survivin can be regarded as a useful prognostic marker for pediatric MPNST and a promising target for therapeutic interventions

Myoepithelial Tumors of Soft Tissues (Figs. 13-35 and 13-36)

Definition: Group of primary soft tissue tumors with morphologic and immunohistochemical similarities to their salivary gland counterparts but arising within soft tissue sites unrelated to salivary glands, and associated with *EWSR1* gene rearrangement.

Synonyms: Parachordoma; ectomesenchymal chondromyxoid tumor of the tongue likely represents a myoepithelial neoplasm of soft tissues (see Section 2, Oral Cavity)

- Primary myoepithelial tumors of soft tissues are uncommon and include benign and malignant neoplasms.
- Classification includes:
 - Soft tissue myoepithelioma:
 - Composed exclusively or predominantly of (benign) myoepithelial cells
 - Soft tissue mixed tumor:
 - Composed of tumors with ductular/glandular differentiation in addition to myoepithelial cells

- Presence of ductular/glandular component separates soft tissue mixed tumor from myoepithelioma
- Ductular/glandular component may be seen in up to 20% of soft tissue myoepithelial tumors.
- Myxoid to chondromyxoid stroma can be seen in myoepithelioma and mixed tumor:
 - Chondro-osseous and adipocytic differentiation can be present.
- Soft tissue myoepithelial carcinoma:
 - Soft tissue neoplasm with myoepithelial differentiation, malignant cytomorphologic features, and invasive growth
 - **Synonym:** Soft tissue malignant myoepithelioma

NOTE: As compared with their salivary gland counterpart, a higher proportion of myoepithelial tumors of soft tissues are malignant.

Soft Tissue Myoepithelial Carcinoma

Clinical Features

- No gender predilection; occur over a wide age range with many cases affecting pediatric ages but develop in adult populations as well
- Majority occurs in soft tissues outside the head and neck, most commonly arising in limbs (upper and lower) and girdle with involvement of the subcutis and deep soft tissues
- Uncommon head and neck tumor:
 - Among more common sites of occurrence include the neck and craniofacial region.
- Symptoms usually include a (neck) mass with or without associated pain.
- Unlike salivary gland myoepithelial carcinoma, the majority of which arise in association with a pleomorphic adenoma (i.e., myoepithelial carcinoma ex pleomorphic adenoma), such an occurrence is rare relative to soft tissue myoepithelial carcinoma, the majority of which occur as a *de novo* malignancy.

Pathology

Gross

- Most are circumscribed but cases may have infiltrative margins

Histology

- At low magnification multinodular or lobular architecture is evident:
 - At the periphery of the lobules the lesion is hypercellular arranged in reticular, trabecular, nests, or solid patterns.

Fig. 13-35. Myoepithelial carcinoma of soft tissue.

A, Resection specimen (partial mandibulectomy) in 23-year-old patient with 4.0-cm mass in the left temporomandibular region. On cut section the mass in part was circumscribed (*arrows*) but had infiltrative margins including into bone (*arrowheads*). Necrotic change appearing as a cystic area is present. **B**, At low magnification the neoplastic proliferation shows fascicular to storiform growth with ill-defined edges and infiltration into skeletal muscle (*left*); lesional cells are characterized by nuclear pleomorphism, hyperchromasia, and increased mitotic activity with varying features including (**C**) epithelioid cells; (**D**) spindle-shaped cells; and (**E**) cells with clear cytoplasm. **F**, Histologic confirmation of osseous invasion was present.

Fig. 13-36. Myoepithelial carcinoma: IHC staining.

Myoepithelial carcinoma of soft tissue, immunohistochemical staining. Most cases show consistent reactivity for (A) cytokeratin (AE1/AE3); (B) CK 8/18 (CAM5.2); and (C) S100 protein. In addition, variable immunoreactivity can be seen for (D) EMA; (E) p63; (F) vimentin; and (G) muscle-specific actin.

- Lesional cells may be epithelioid, clear, spindle-shaped, or plasmacytoid:
 - Characterized by cytomorphologic heterogeneity:
 - Epithelioid type predominates
 - Majority of cases are composed of more than one myoepithelial cell type
 - Cytologic atypia of at least moderate degree is present, including nuclear enlargement, vesicular to coarse-appearing nuclei, and variably prominent nucleoli.
- Increased mitotic activity, tumor necrosis, and lymph-vascular invasion may be present.
- Stromal component includes myxoid change and/or hyalinization.
- Cartilaginous differentiation and metaplastic ossification may be present.

Immunohistochemistry:

- Lesional cells consistently reactive for cytokeratins (AE1/AE3, CAM5.2, PAN-K) and S100 protein
- EMA positive in majority of cases
- Variable calponin, p63, and GFAP staining
- Less consistent reactivity for SMA, MSA, CD10, and vimentin positive
- Loss of expression of *SMARCB1* (INI1) in subset of cases lacking *EWSR1* gene rearrangements and with rhabdoid morphology (sole pattern or in part)
- Immunoreactivity may be present for CD99.
- Desmin, CD34, TLE1, and brachyury are typically negative.
- *PLAG1* (nuclear) staining present in benign myoepithelial soft tissue tumors with ductal differentiation
- Cytogenetics and molecular genetics:
 - Myoepithelial carcinomas:
 - Demonstrate *EWSR1* gene rearrangement with a variety of different fusion partners, most notably *POU5F1* and *PBX1*:
 - Such rearrangements more common in malignant tumors
 - *EWSR1-POU5F1* tumors occur in younger patients
 - *EWSR1-PBX1* tumors have sclerotic appearance and clear cell morphology
 - ◻ Too few cases analyzed to make definitive correlations between rearrangement(s) to pathology and/or biologic behavior
 - Rare cases with t(19;22)(q13;q12) result in *FUS* gene rearrangement.
 - Lack *PLAG1* gene rearrangement
 - Presence of *EWSR1* and absence of *PLAG1* rearrangements support that such tumors are unrelated to their salivary gland counterparts.

- Benign myoepithelial tumors:
 - *PLAG1* gene rearrangement found in cases with ductal differentiation:
 - Supporting concept that such soft tissue tumors are genetically related to their salivary gland counterparts

Differential Diagnosis

- In cervical neck, must exclude origin from primary salivary gland (e.g., parotid) myoepithelial tumor/carcinoma:
 - See Section 6, Salivary Glands
 - Salivary gland myoepithelial carcinoma not associated with *EWSR1* gene rearrangement
- Extraskelatal myxoid chondrosarcoma:
 - *NR4A3* rearrangement, which is absent in myoepithelial carcinoma of soft tissues
- Chordoma
- Epithelioid malignant peripheral nerve sheath tumor
- Synovial sarcoma (poorly differentiated)
- Undifferentiated carcinoma
- Ewing family of tumors

Treatment and Prognosis

- Wide surgical resection for localized tumors and adjuvant radiotherapy with or without nodal dissection
 - Use of chemotherapy is unproven and appears in limited studies to offer no added benefit.
- May recur locally
- Metastasizes in 40% to 50% of cases:
 - Lymph nodes, lungs, bone including clivus
- Appears more aggressive behavior occurs in pediatric ages than in adult population, including death from disease

Rhabdomyosarcoma (RMS)

Definition: Malignant neoplasm showing skeletal muscle differentiation.

- RMS is covered in greater detail in Section 3, Pharynx.

Leiomyosarcoma (LMS)

Definition: Malignant neoplasm with smooth muscle differentiation.

- LMS is covered in greater detail in Section 1, Sino-nasal Tract.

Liposarcoma

Definition: Malignant neoplasm with adipocyte cell differentiation.

- For more complete discussion see Section 5, Larynx and Trachea.

Angiosarcoma

Definition: Malignant neoplasm with endothelial cell differentiation.

- For more complete discussion see Section 1, Sinonasal Tract.

Synovial Sarcoma

Definition: Mesenchymal tumor with variable degree of epithelial differentiation characterized by specific chromosomal translocation $t(x;18)(p11;q11)$, leading to formation of an SS18-SSx fusion.

- For more complete discussion see Section 3, Pharynx.

METASTATIC CERVICAL CARCINOMA WITH AN UNKNOWN PRIMARY TUMOR (MCCUP)

(Figs. 13-37 through 13-46)

Definition: Overt neck mass harboring a cytologically or histologically proven metastatic carcinoma in the absence of signs and symptoms of a primary neoplasm or of a clinically detectable mass and includes:

- No history of previous malignancy or cancer ablation of any indeterminate lesion
- No history of definite symptoms related to a specific organ system

Fig. 13-37. Fine needle aspiration, metastatic squamous cell carcinoma.

Fine-needle aspiration material of metastatic keratinizing squamous cell carcinoma from lateral neck masses include (A) well-differentiated squamous cell carcinoma characterized by cells with individual cell keratinization and hyperchromatic, irregular nuclei; background neutrophilic infiltrate is present; (B) moderately differentiated squamous cell carcinoma characterized by cohesive groupings of malignant squamous cells with atypical nuclei showing increased nuclear-to-cytoplasmic ratio, nuclear membrane irregularities, and marked hyperchromasia. The primary carcinomas for the metastases in A and B originated from laryngeal keratinizing squamous cell carcinomas. C, Poorly differentiated carcinoma characterized by clusters and sheets of malignant squamous cells with tight nuclear overlapping, marked hyperchromasia, increased nuclear-to-cytoplasmic ratio, and prominent nucleoli. All examples were p16 and EBER negative (not shown). The primary carcinoma for the metastasis in C originated from the oral cavity.

Fig. 13-38. Metastasis to lateral cervical neck.

Resection specimen of a lateral neck mass showing a cystic and solid mass.

Fig. 13-39. Metastatic cystic keratinizing squamous cell carcinoma.

Multicystic epithelial-lined lesion composed of cells with readily identifiable squamous differentiation. Although p16 staining was negative, the primary carcinoma was found in the ipsilateral tonsil.

Fig. 13-40. Metastatic nonkeratinizing carcinoma.

A, Fine-needle aspiration of metastatic nonkeratinizing carcinoma characterized by clusters of malignant basaloid cells with pleomorphic, hyperchromatic nuclei lacking evidence of squamous differentiation. **B,** Cell block from this aspirate shows clusters of nonkeratinizing carcinoma. **C,** p16 staining including strong nuclear and cytoplasmic staining represents a surrogate marker for HPV16 and its presence is highly predictive of origin from the oropharynx. A small primary base of tongue carcinoma was subsequently identified.

Fig. 13-41. Metastatic cystic nonkeratinizing carcinoma.

A, Resected lymph node replaced by cystic metastatic nonkeratinizing carcinoma with central cystic change and associated necrotic debris. **B**, Malignant epithelium characterized by pleomorphic and hyperchromatic cells with increased cellularity, increased mitoses, and loss of polarity. **C**, Diffuse and strong nuclear and cytoplasmic p16 immunoreactivity. A primary tonsillar carcinoma was detected by radiologic imaging (see next illustration), prompting biopsy with histologic confirmation.

- No clinical or laboratory evidence of a primary neoplasm

Clinical

- Constitutes approximately 3% of all malignant neoplasms
- Represents 2% to 9% of all head and neck cancers
- Demographics are changing due to increasing incidence of HPV-associated head and neck carcinomas with stabilization in the incidence of carcinomas associated with tobacco and alcohol overuse.
- HPV-associated metastatic carcinoma:
 - No gender predilection
 - Younger age groups as compared with squamous cell carcinomas associated with tobacco/alcohol use
 - Caucasian >>>> African American
- Often no known risk factors (usually nonsmokers, nondrinkers)
- Site(s): oropharynx (base of tongue; tonsil)
- Histology: nonkeratinizing carcinoma predominantly composed of basaloid cells
- p16 positive
- Better disease-free and overall survival
- Often present with higher clinical stage disease: more nodal metastasis
- Carcinoma associated with tobacco and alcohol overuse:
 - More common in men than women
 - Most frequently seen in the fifth to seventh decades of life
 - Caucasian = African American
 - Associated with tobacco and/or alcohol use/abuse

Fig. 13-42. Metastatic HPV-associated carcinoma to the cervical neck.

A, Axial T2-weighted MR image showing a level IIa heterogeneous lymph node (*arrow*) and a level IIb homogeneous lymph node (*arrowhead*). In this imaging the lingual tonsils are symmetric without an identifiable mass. **B**, PET-CT fusion image in the same patient as part A showing the level IIa lymph node to be heterogeneously hypermetabolic, implying nodal necrosis (*long arrow*), the level IIb lymph node to be uniformly hypermetabolic (*arrowhead*), and the presence of asymmetric increased hypermetabolism in the left (ipsilateral) lingual tonsil (*short arrow*). A subsequent biopsy of the lingual tonsil confirmed a primary HPV-associated carcinoma.

Fig. 13-43. Metastatic nasopharyngeal (EBV-associated) carcinoma, nonkeratinizing differentiated type.

A, Metastatic cystic nonkeratinizing carcinoma of nasopharyngeal origin replacing the involved lymph node and showing central cystic change with associated necrotic debris. **B**, At higher magnification the malignant epithelial cells are nonkeratinizing and histologically similar to carcinomas of oropharyngeal origin.

Fig. 13-43, cont'd

C, Lesional cells are positive for EBER (and p16 negative, not shown), supporting origin from the nasopharynx.

- Site(s): all mucosal sites of the upper aerodigestive tract
 - Histology: keratinizing squamous cell carcinoma
 - p16 negative
 - Worse disease-free and overall survival
 - Often present with lower clinical stage disease; less nodal metastasis
- Most common clinical manifestation of a MCCUP is that of a unilateral, fixed, painless neck mass enlarging over several months:
 - Unilateral nodal involvement is most common, occurring in up to 52% of cases.
 - Bilateral nodal involvement seen in approximately 10% of cases
- Location of metastasis in patients with MCCUP:
 - Level II represents the most frequent cervical metastatic site occurring in more than 50% of patients
 - After level II, levels I and III are the next most common metastatic sites.
 - Lower neck and/or supraclavicular lymph node metastases also common but more frequently associated with a primary malignancy below the clavicle (i.e., thorax, abdomen)
- Lymphatic drainage to the cervical lymph nodes is predictable, and the anatomic location of the metastatic focus assists in the search for the primary focus (Table 13-5).
- AJCC staging for MCCUP is detailed in Table 13-6.
- Majority of metastatic carcinomas to the cervical lymph nodes take origin from a head and neck primary tumor and therefore the most common histologic appearance is that of a squamous cell carcinoma, including keratinizing and nonkeratinizing.
- By far, the oropharynx (tonsil and base of tongue) and nasopharynx, collectively referred to as Waldeyer tonsillar ring, are areas harboring the occult primary tumor in the majority of squamous carcinomas metastatic to the neck; other common but less frequent sites of the occult tumor include thyroid, hypopharynx, and larynx (supraglottic region):
 - There is no correlation between the size of the primary carcinoma and the size of the metastasis such that the primary carcinoma may be only a few millimeters in size, whereas the metastasis may be several centimeters in size:
 - Given the potential of the primary carcinoma to be extremely small, it may not be possible to detect the primary by clinical, radiologic, and pathologic examination.
 - Even in the absence of identifying the primary carcinoma, a diagnosis of primary carcinoma arising in a branchial cleft cyst should not be invoked (see later under differential diagnosis).
- Carcinomas arising in the oropharynx and nasopharynx often are viral associated, including:
 - HPV-associated carcinoma arising from the oropharynx
 - EBV-associated carcinoma arising from the nasopharynx
- Laboratory findings:
 - Generally of limited utility as laboratory findings in the setting of MCCUP are not sensitive or specific
 - Serologic studies for EBV are abnormal in nasopharyngeal carcinomas (nonkeratinizing types)
 - Elevated *serum* calcitonin typically present in association with medullary thyroid carcinoma; however:
 - Serum calcitonin is not elevated in nonthyroid neuroendocrine carcinomas (of mucosal sites of the head and neck) although *tissue* calcitonin may be present by immunohistochemical evaluation in nonthyroid neuroendocrine neoplasms.
- Diagnostic work-up for a patient with a unilateral fixed neck mass includes:
 - Fine-needle aspiration biopsy (FNAB) or open biopsy:
 - See later under [Pathology](#).
 - Preferable to obtain basic imaging of the head and neck prior to FNAB or open biopsy
 - Radiographic imaging:
 - Should precede panendoscopy as information generated may assist in directing biopsies
 - Includes contrast-enhanced computed tomography (CECT) and positron emission tomography (PET) with or without computed

Fig. 13-44. Metastatic nasopharyngeal (EBV-associated) carcinoma, nonkeratinizing undifferentiated type.

A, Left panel, Resected enlarged cervical neck lymph node harboring metastatic carcinoma that at low magnification shows no readily apparent neoplasm due to an absence of a desmoplastic response. **Right panel,** Even at higher magnification the identification of the neoplastic cells can be difficult given the absence of a desmoplastic response.

B, At higher magnification the malignant cells are composed of enlarged vesicular nuclei with prominent nucleoli. **C,** The malignant epithelial cell component is cytokeratin (AE1/AE3) reactive and **(D)** EBER positive. A primary nasopharyngeal carcinoma was detected by radiologic imaging (see next illustration). The absence of a desmoplastic response may occur in primary Waldeyer ring viral-associated carcinomas, including those originating in the oropharynx (HPV positive) as well as from the nasopharynx (EBV positive) and in the metastatic foci.

tomography (CT) and magnetic resonance imaging (MRI):

- Enhances the assessment of neck disease
- Assists in detecting the primary lesion
- CT provides anatomic information
- PET provides metabolic information
- Up to 30% of neck nodes pathologically diagnosed are clinically not palpable (i.e., N0) and necks are upstaged by CT in 20% to 30% of patients
- Sensitivity and specificity of PET scans in detection of primary cancer in patients with MCCUP reported to be 88% and 75%, respectively

- PET scans have higher false positive than false negative rate:
 - Tend to overread tonsillar cancers with a false positive rate of 39%
 - False positive rate also higher in base of tongue with sensitivity of 82% compared with 91% in other head and neck sites
 - Lack of sensitivity in base of tongue thought to occur from the high baseline levels of fluorodeoxyglucose uptake in that area
 - Highest accuracy of PET scans in tumors of the larynx and hypopharynx with sensitivity and specificity of 100%

Fig. 13-45. Primary and metastatic nasopharyngeal carcinoma.

Axial fused PET/CT images show a large nasopharyngeal cancer with high PET activity with a left level IIB node (**A**) and a left IIA node (**B**). The level IIA node was a metastatic carcinoma node. The level IIB node, with similar activity, was a reactive node. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 2377, Fig. 38-107.)

- PET/CT:
 - Combination of the two modalities have highest yield in discovering the primary head and neck cancer
 - PET/CT superior to either PET or CT
 - Widely available and represents the preferred imaging modality in MCCUP
 - In addition, benefits include ability to detect unexpected contralateral nodal disease, synchronous malignancies, and distant nodal involvement.
- Metabolic imaging:
 - Neoplasms have increased metabolic activity with respect to surrounding normal mucosa.
 - Isotope ^{18}F -fluorodeoxyglucose (FDG), a glucose analogue, enters cells using normal transport mechanisms
 - The application of FDG uses the fact that glucose metabolism (i.e., FDG uptake) is increased in malignant cells but cannot be further metabolized, remaining in the tumor tissues.
 - Imaging modalities using FDG include positron emission tomography (PET) (FDG-PET):
 - ◻ Increases the detection of primary cancer site by up to 54%
- Chest radiograph:
 - Screening method for primary, metastatic, and secondary primary lung lesions
- Panendoscopy:
 - Includes assessment of the nasopharynx, oral cavity, oropharynx, hypopharynx, larynx, esophagus, and tracheobronchial tree
 - Any mucosal abnormality should be biopsied.
 - If no abnormalities are grossly seen, random biopsies (also referred to as random-guided, directed, or blind biopsies) are indicated.
- Open biopsy:
 - May be required in the face of a neck suspicious for metastatic carcinoma with nondiagnostic fine-needle aspiration biopsy, negative panendoscopic evaluation (clinically and histologically negative)
 - Should be performed in intraoperative consultation (i.e., frozen section) with preparations in place to treat the neck definitively in the presence of a malignant diagnosis by frozen section
- Etiologic factors relate to the development of squamous carcinoma of the head and neck and, as such, are linked to:

Fig. 13-46. Metastatic oropharyngeal “lymphoepithelial-like” carcinoma.

A, Metastatic cystic carcinoma to a cervical neck lymph node. **B,** At higher magnification the histology of the carcinoma is similar to nasopharyngeal carcinoma, nonkeratinizing undifferentiated type, but is **(C)** p16 positive and **(D)** EBER negative. The primary carcinoma originated from the oropharynx. This example illustrates the overlapping histologic findings shared by oropharyngeal HPV-associated nonkeratinizing and undifferentiated carcinomas and nasopharyngeal EBV-associated nonkeratinizing and undifferentiated carcinomas. In the presence of an unknown primary carcinoma, cervical lymph node metastases with such histomorphologic should prompt evaluation for p16 and EBER.

- Tobacco and alcohol use
- Viruses, including HPV linked to oropharyngeal cancers and EBV lined to nasopharyngeal cancers

Pathology

Fine-Needle Aspiration Biopsy (FNAB)

- In most cases there is increased cellularity with the cytologic features varying depending on the degree of differentiation:
 - Keratinizing squamous cell carcinoma:
 - Cohesive groupings of cells
 - Cells showing individual cell keratinization characterized by the presence of atypical nuclei with increased nuclear-to-cytoplasmic ratio, nuclear membrane irregularities, and marked hyperchromasia

- Dyskeratotic cells, best appreciated by Papanicolaou stain, have a bright orange color
- Presence of rare, immature atypical nonkeratinized cells with increased nuclear-to-cytoplasmic ratio may be identified.
- Nonkeratinizing squamous cell carcinoma:
 - Sheets or loose groupings of cells
 - Nuclear crowding
 - Cells are more irregular than those of well-differentiated carcinomas with higher nuclear-to-cytoplasmic ratio and large, pleomorphic nuclei with granular-appearing chromatin and large nucleoli.
 - Given these overall findings many of these cancers are considered poorly differentiated; however, in fact, these nonkeratinizing

TABLE 13-5 Lymph Node Levels and Possible Primary Sites for Metastasis

Lymph Node Level	Drainage
I (submental; submandibular)	Anterior oral cavity Anterior nasal cavity
II (upper jugular)	Oral cavity Oropharynx Nasopharynx Larynx Hypopharynx Parotid gland
III (midjugular)	Oropharynx Nasopharynx Larynx Hypopharynx
IV (lower jugular)	Larynx Hypopharynx Thyroid Esophagus
V (posterior triangle)	Nasopharynx Posterior scalp
VI (anterior compartment)	Thyroid Larynx (subglottis) Hypopharynx Esophagus
Preauricular (not assigned a level)	Skin of upper face and temple
Retropharyngeal (not assigned a level)	Nasopharynx Hypopharynx Larynx
Supraclavicular (not assigned a level)	Infraclavicular and subdiaphragmatic
Viral-associated carcinomas:	
HPV-associated	Oropharynx
EBV-associated	Nasopharynx

Modified from Chang SS, Califano J: Metastatic cancer of the neck from an unknown primary site. In Harrison LB, Sessions RB, Kies MS, editors: Head and neck cancer: a multidisciplinary approach, ed 4, Philadelphia, 2014, Lippincott Williams & Wilkins, pp 319-327.

carcinomas recapitulate the tonsillar crypt epithelium and while lacking keratinization are considered as differentiated carcinomas and not poorly differentiated carcinomas.

- Additional findings may include the presence of necrotic debris and numerous neutrophils.

Gross

- Variable including solid gray-white mass to cystic lesion with associated necrosis and hemorrhage.

Histology

- In the setting of MCCUP, metastatic squamous cell carcinoma is the most common:

TABLE 13-6 AJCC Staging for Metastatic Cervical Carcinoma with an Unknown Primary Tumor (MCCUP)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1*	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2*	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension; or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension; or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N2a*	Metastasis in a single ipsilateral lymph node more than 3 cm, but not more than 6 cm in greatest dimension
N2b*	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
N2c*	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N3*	Metastasis in lymph node more than 6 cm in greatest dimension
M0	No distant metastasis
M1	Distant metastasis

*Note: A designation of "U" or "L" may be used for any N stage to indicate metastasis above the lower border of the cricoid (U) or below the lower border of the cricoid (L). Similarly, clinical/radiologic ECS should be recorded as E- or E+, and histopathologic ECS should be designated as En, Em, or Eg. Used with permission from Edge et al: AJCC cancer staging manual, ed 7, New York, 2010, Springer-Verlag, p 25.

- 45% to 70% of all metastases in MCCUP are squamous cell carcinomas and morphologically include:
 - Nonkeratinizing squamous cell carcinoma
 - Keratinizing squamous cell carcinoma
 - Undifferentiated carcinoma
- Less common morphologic types include:
 - Adenocarcinoma
 - Thyroid carcinoma
 - Melanoma
- Metastatic (cystic) squamous cell carcinoma, nonkeratinizing and keratinizing:
 - There is partial or complete replacement of the lymph node by an epithelial-lined structure often with central cystic change and associated necrotic debris.
 - Epithelium varies from areas that are bland composed of uniform cells lacking pleomorphism, crowding, or loss of polarity to overtly malignant-appearing epithelium composed of pleomorphic cells with increased cellularity, mitoses, and a loss of polarity

- Keratinization in the form of individual cell varies from completely absent to focally present to more overtly present.
- Histologic appearance strongly suggests origin from oropharynx (tonsil and base of tongue):
 - p16 immunoreactivity including strong and diffuse nuclear and cytoplasmic staining is a surrogate marker for HPV16 and highly predictive of origin from the oropharynx.
 - p16 staining often allows for differentiating a metastatic nonkeratinizing carcinoma (p16 positive) from branchial cleft cyst (p16 negative); however, p16 may be overexpressed in almost 50% of benign branchial cleft cysts potentially limiting the diagnostic utility of p16 in this setting; in such an occurrence molecular testing (in situ hybridization, PCR) would be necessary to confirm presence of HPV and the malignant nature of the cyst
 - Proliferation markers (i.e., Ki67) show increased proliferation rates throughout the epithelium.
- Carcinomas with similar histologic findings may originate from other head and neck sites, including the nasopharynx:
 - Nasopharyngeal carcinoma, keratinizing type:
 - Usually does not present as a MCCUP
 - Not associated with Epstein-Barr virus (EBV) and typically negative for in situ hybridization for Epstein-Barr encoded RNA (EBER)
 - Nasopharyngeal carcinoma, nonkeratinizing differentiated type:
 - May present as MCCUP
 - Associated with EBV and positive for EBER (nuclear staining)
- Metastatic undifferentiated carcinoma:
 - There is partial or complete replacement of the lymph node by cystic and/or solid epithelial proliferation characterized by cells with enlarged nuclei, vesicular chromatin, and prominent eosinophilic nucleoli.
 - Keratinization typically absent
 - Histologic appearance strongly suggests origin from nasopharynx (i.e., nasopharyngeal carcinoma, nonkeratinizing undifferentiated type); however, similar histology may occur in carcinoma originating from the oropharynx and should include staining for carcinomas originating from the nasopharynx and oropharynx:
 - In situ hybridization for Epstein-Barr encoded RNA (EBER) including diffuse and strong nuclear staining confirms origin from the nasopharynx.
 - p16 immunoreactivity including strong and diffuse nuclear and cytoplasmic staining confirms origin from the oropharynx.

Differential Diagnosis

- Branchial cleft cysts:
 - Presence of morphologically malignant epithelium would exclude a diagnosis of branchial cleft cyst
 - p16 reactivity:
 - p16 reactivity in the branchial cleft cysts is usually negative, showing patchy positivity, or is characterized by focal, strong staining limited to involvement of the superficial squamous epithelium; in comparison, diffuse and strong p16 staining characterizes metastatic oropharyngeal carcinoma.
 - p16 may be overexpressed in almost 50% of benign branchial cleft cysts potentially limiting the diagnostic utility of p16 in this setting; in such an occurrence molecular testing (in situ hybridization, PCR) would be necessary to confirm presence of HPV and the malignant nature of the cyst.
 - Ki67 (MIB1) reactivity:
 - Branchial cleft cysts typically show a low proliferation rate (less than 5%) even if inflamed.
- Carcinoma arising in a branchial cleft cyst (branchiogenic carcinoma; malignant branchioma):
 - Criteria used for the diagnosis of a branchiogenic carcinoma include:
 - The metastatic tumor occurs along the line extending from a point anterior to the tragus along the anterior border of the sternocleidomastoid muscle to the clavicle.
 - Histology supports origin from a branchial cleft–derived structure.
 - Histology supports carcinoma arising in the wall of an epithelial-lined cyst.
 - A minimum of 5-year follow-up demonstrates no evidence of a primary source for this neoplasm.
 - Despite the fulfillment of these criteria it is highly unlikely that carcinoma arises in a branchial cleft cyst: rather, all these cystic squamous cell carcinomas take origin from a primary tumor in Waldeyer tonsillar ring with the primary neoplasm being so small as to defy clinical detection but nevertheless is capable of metastasizing.
 - Factors weighing against the existence of a branchiogenic carcinoma include:
 - Branchial cleft anomalies are rare.
 - As almost all patients with MCCUP present with neck masses of recent onset, a large number of subclinical branchial cleft cysts would have to be present to account for the number of cases of MCCUP.

- Presence of p16 reactivity:
 - Metastatic oropharyngeal nonkeratinizing SCC shows diffuse, strong p16 and HPV16 DNA positivity while p16 reactivity in the branchial cleft cysts is negative, shows patchy positivity, or is characterized by focal, strong staining limited to involving the superficial squamous epithelium although as previously noted p16 may be overexpressed in almost 50% of benign branchial cleft cysts; molecular testing (in situ hybridization, PCR) would be necessary to confirm presence of HPV and the malignant nature of the cyst.
- Benign intranodal inclusions:
 - See Section 6, Salivary Glands, for a discussion on the presence of benign nonneoplastic salivary gland parenchyma in periparotid lymph nodes.
 - See Section 8, Thyroid Gland, for a discussion relative to intranodal thyroid epithelium.
 - Intranodal nevi
 - Intranodal benign spindle cell neoplasms such as intranodal myofibroblastoma
- Cervical thymic cyst

Detection of the Primary Neoplasm

- Success rate of finding the primary neoplasm varies from approximately 10% to 82%.
- Nearly 60% of detected primary neoplasms originate from Waldeyer tonsillar ring (i.e., oropharynx, nasopharynx).
- Prior irradiation significantly lowers the incidence of detecting primary cancer.
- Most common primary malignancy below the clavicle is the lungs followed by the gastrointestinal tract.
- Tonsillectomy:
 - Appropriate use of tonsillectomy remains controversial.
 - Detection rate of carcinoma in tonsillectomy specimens when radiographic imaging is negative varies from different institutes, with some reports showing a high prevalence rates (up to 39%) for tonsillary primary tumors in the face of unknown metastatic squamous cell carcinoma to others reporting low prevalence rates (10%).
 - If a tonsillectomy is performed, the entire resected specimen should be submitted for histologic evaluation:
 - Will increase detection of primary carcinoma, especially very small ones
- Micrometastasis:
 - The definition of what constitutes micrometastasis is not completely defined but deposits measuring 3 mm or smaller are considered as qualifying as micrometastatic tumor.

- Micrometastatic deposits are not clinically detectable but are identified by the pathologist following neck dissection with tissue examination.
- Micrometastatic deposits may be visualized by light microscopy or may require immunohistochemical stains for cytokeratin.
- The clinical import of micrometastatic deposits remains unknown.
- Unless identified by light microscopy, at present there is no justification for immunohistochemical evaluation of neck dissections for the identification of micrometastatic deposits.

Treatment and Prognosis

- Management is a discussion on advanced stage squamous cell carcinoma as patients are either Stage III or IV since by definition nodal metastasis precludes Stages I and II.
- Similar to advanced stage squamous cell carcinomas of other head and neck sites, patients are treated by combined modality therapy, including surgery and radiation:
 - Stage III:
 - Surgery includes a comprehensive neck dissection (levels I to V) that in most cases can include preservation of the spinal accessory nerve without compromise of local control.
 - A majority of patients are treated by combined surgery and radiation because of:
 - Inaccuracy of clinical staging to predict microscopic disease
 - Frequent occurrence of extracapsular nodal spread
 - Concern for the development of a late primary tumor in the head and neck
 - A minority of patients can be eligible for single modality therapy.
 - Stage IV disease, including N2 (N2b or N2c) to N3 warrants comprehensive neck dissection with radiation given either before or after surgery.
- Intensity-modulated radiotherapy (IMRT) used primarily in patients with ipsilateral positive nodes:
 - Patients usually receive weekly concomitant cisplatin during course of IMRT.
- Clinical staging and pathologic staging can differ considerably:
 - In unknown primary neck disease that is clinically N1, 45% of patients are found to have multiple nodes by pathologic evaluation after surgery (N2b).
 - In comparing single-node disease (N1 or N2a) 57% of patients have multiple nodes on neck dissection.
- Survival rates vary widely and dependent on many factors, not the least of which is presence or absence of HPV-positive cancers:

- 60% to 90% 5-year survival rates
- 60% to 90% 5-year locoregional control
- Prognostic factors include:
 - Stage of disease:
 - Single most reliable prognostic factor
 - Decrease in 3-year survival rates from 79% to 38% with progression from NX neck to N+ neck
 - HPV positive:
 - Generally have better survival rates
 - Location of the lymph node:
 - Supraclavicular nodal or low cervical nodal involvement associated with worse prognosis rarely cured by any therapeutic intervention
 - Patients with disease in the lower neck have 27% rate of distant metastasis compared with a 13% risk of distant metastasis in patients with disease in the upper neck.
 - Histologic appearance:
 - Metastatic adenocarcinomas (except papillary thyroid carcinoma) have worse survival rates.
 - Metastatic oropharyngeal (HPV-associated) carcinoma and metastatic nasopharyngeal (EBV-associated) carcinoma tend to have better survival than non-viral-associated metastatic carcinomas.
 - Extranodal extension:
 - Spread of metastasis to extranodal soft tissues associated with increased neck failure (i.e., recurrent neck disease), distant metastases, and decreased disease-free survival
 - Presence of distant metastasis:
 - Significantly decreases survival rate
 - Desmoplastic stromal response:
 - Presence of nodal desmoplasia in response to metastatic disease is associated with increased risk of recurrent neck disease.
- Recurrence:
 - Recurrence in patients with MCCUP is an ominous prognostic factor
 - Can be in the ipsilateral or contralateral neck
 - Patients can also develop second primary lesion.
- Typically, metastatic carcinoma to a supraclavicular lymph node originates from a primary source below the clavicle (e.g., thorax, GI tract, others).
- Virtually every other organ may be the primary focus of a metastasis to the head and neck but among the more common primary malignancies to metastasize to the head and neck from a primary malignancy not of the head or neck include:
 - Kidney
 - Prostate
 - Melanoma (often cutaneous but also noncutaneous types)
- As a general rule, when confronted with a malignancy in a head and neck site posing difficulties in histologically classifying it to that specific site, pathologists should give consideration to the possibility of its representing metastasis from a distant (not a head or neck) site:
 - In such a situation morphologic features and immunohistochemical staining may allow for determination of the primary (non-head and neck) site of origin.
 - At the time of metastasis to the head and neck, the primary (non-head and neck) malignancy may be occult or may have occurred years previously.
- Other tumor types that can metastasize to lymph nodes in the presence of an occult primary neoplasm include:
 - Metastatic melanoma:
 - Primary tumor may be of cutaneous or mucosal origin.
 - Primary melanoma may precede the metastasis (including years to decades previously) or synchronously with the metastasis.
 - Immunohistochemistry assists in the diagnosis (e.g., S100 protein, HMB45, melan-A, tyrosinase, MITF1, and vimentin).
 - Metastatic thyroid carcinomas, including papillary carcinoma and medullary carcinoma:
 - Immunohistochemistry assists in the diagnosis:
 - Papillary thyroid carcinoma: thyroglobulin positive (as well as cytokeratins and thyroid transcription factor 1)
 - Medullary thyroid carcinoma: calcitonin, synaptophysin, and chromogranin positive (as well as cytokeratins and thyroid transcription factor 1)
 - **NOTE:** Rarely, neuroendocrine carcinomas from a primary head and neck site (e.g., larynx) may metastasize to cervical neck lymph nodes in the absence of a known primary malignancy; moderately

SECONDARY TUMORS TO THE NECK (OTHER THAN CARCINOMA FROM HEAD AND NECK SITES)

- Metastatic tumors to the neck are not limited to origin from a head and neck neoplasm but may represent primary occult neoplasms from organ systems in the thorax, abdomen, and pelvis:
 - Most common primary site for a metastatic tumor originating from below the clavicle is the lungs

- differentiated NEC (atypical carcinoid) often originates in the supraglottis, where it may be clinically quiescent and give rise to metastatic nodal disease; such NECs may share overlapping light microscopic features and immunohistochemical staining including calcitonin with medullary thyroid carcinoma.
- Differentiation is predicated on identifying the primary malignancy and determining if serum calcitonin is elevated, a finding associated with medullary thyroid carcinoma but not laryngeal (and other non-thyroid-based) neuroendocrine carcinomas.
 - Metastatic adenocarcinoma from above and below the diaphragm:
 - It is extremely uncommon for a primary salivary gland neoplasm to manifest as a metastatic tumor in a cervical neck lymph node without a clinically apparent mass at the site of origin.
 - In the head and neck, difficulty in histologically classifying a given tumor or the presence of an unusual histologic appearance should alert the pathologist to the possibility that the neoplasm represents a metastasis from a distant site.
 - Primary carcinoma for a metastatic tumor in supraclavicular lymph nodes is usually from below the clavicle (e.g., intrathoracic or intra-abdominal).
 - Most common primary site for a metastatic tumor originating from below the clavicle is the lungs followed by the gastrointestinal tract, but virtually every other organ may be the primary focus of a metastasis to the head and neck, including those in which the primary neoplasm may be clinically occult, such as renal cell carcinoma and prostatic adenocarcinoma, although these malignancies are more likely to metastasize to a mucosal or osseous site in the head and neck rather than to a lymph node:
 - Immunohistochemistry may be necessary in the identification of a metastasis from a remote primary site:
 - For lung adenocarcinoma: TTF1 and Napsin A
 - For gastrointestinal carcinoma: CK20, CDX2, villin
 - For renal cell carcinoma: CD10, renal cell marker, PAX8, and racemase
 - For prostatic adenocarcinoma: prostate specific antigen, prostatic alkaline phosphatase, and prostein

Embryology, Anatomy, and Histology of the Larynx and Trachea

LARYNX

Embryology

- Epithelium and glands of the larynx arise from the endoderm lining the laryngotracheal groove.
- Supraglottic larynx arises from the third and fourth branchial arches.
- Glottis and subglottic larynx arise from the sixth branchial arch.
- Cartilage, muscle, and other connective tissue elements develop from the mesenchyme around the foregut:
 - Thyroid, cricoid, arytenoid, corniculate, and cuneiform cartilages derived from the fourth and sixth branchial arch
 - Greater cornu and inferior part of the body of the hyoid bone derived from the third branchial arch cartilage; lesser cornu and superior part of the body of the hyoid bone derived from the second branchial arch cartilage
 - Intrinsic muscles of the larynx muscles derived from the fourth and sixth branchial arch
 - Superior laryngeal and recurrent laryngeal nerves (both branches of the vagus nerve) are derived from the fourth and sixth branchial arch.

Anatomy (Figs. 14-1 through 14-5)

Anatomic Borders

- Superior border:
 - Tip of epiglottis
- Inferior border:
 - Inferior rim of the cricoid cartilage
- Anterior border:
 - Lingual surface of epiglottis (vallecula), thyrohyoid membrane, anterior commissure, thyroid cartilage, cricothyroid membrane, and the anterior arch of the cricoid
- Posterior border:
 - Posterior commissure, arytenoid and interarytenoid space, and the mucoperichondrium overlying the cricoid cartilage
- Lateral border:
 - Aryepiglottic folds

Anatomic Compartments

- Supraglottis:
 - Extends from the tip of the epiglottis to a horizontal line passing through the apex of the ventricle
 - Structures in this compartment include:
 - Epiglottis (lingual and laryngeal aspects), aryepiglottic folds, arytenoids, false vocal cords, and ventricle
 - Supraglottic larynx arises from the third and fourth branchial arches.
- Glottis:
 - Extends from the ventricle to approximately 0.5 to 1.0 cm below the free level of the true vocal cord and includes the anterior and posterior commissures and the true vocal cord:
 - Glottic portion of the larynx arises from the sixth branchial arch.
- Subglottis:
 - Extends from approximately 0.5 to 1.0 cm below the level of the true vocal cord to the inferior rim of the cricoid cartilage:
 - Subglottic larynx arises from the sixth branchial arch.
- Paralumenal spaces
 - Represent potential spaces that lie between the laryngeal cartilages and ligaments and membranes that support them
 - Three main paralumenal spaces include:
 - Pre-epiglottic space
 - Paraglottic space
 - Subglottic space
- Pre-epiglottic space:
 - Not a space but represents a roughly triangular area lying anterior to the epiglottic cartilage that is filled with adipose tissue and loose connective tissue bounded:
 - Anteriorly by hyoid bone, thyroid cartilage, and thyrohyoid membrane
 - Posteriorly by epiglottic cartilage and thyrohyoid ligament
 - Superiorly by hypoepiglottic ligament forming the base
 - Contains lymphatics and blood vessels but no lymph nodes

Fig. 14-1. Anatomic borders of the larynx.

(From Standing S: *Gray's anatomy*, ed 40, Edinburgh, 2009, Elsevier Churchill Livingstone, p 581, Fig. 34.5B.)

Fig. 14-2. Anatomic compartments of the larynx.

(From Standing S: *Gray's anatomy*, ed 40, Edinburgh, 2009, Elsevier Churchill Livingstone, p 582, Fig. 34.6.)

Fig. 14-3. Sagittal section of larynx.

(Redrawn from Sobotta J: *Atlas der anatomie des menschen in 2 volumes*, ed 20, Munich, Germany, 1975, Urban & Fischer Verlag, Fig. 769.)

Fig. 14-4. Cross-section of larynx at level of vocal folds.

(Redrawn from Sobotta J: *Atlas der anatomie des menschen in 2 volumes*, ed 20, Munich, Germany, 1975, Urban & Fischer Verlag, Figs. 770, 771.)

- Malignancies of laryngeal surface of the epiglottis may invade fat and areolar tissue of pre-epiglottic space.
- Paraglottic space:
 - Not a space but represents an area deep to the true and false vocal cords that contains adipose tissue and loose connective tissue bounded:
 - Inferiorly by conus elasticus (i.e., cricovocal membrane)
 - Laterally by thyroid cartilage
 - Medially by quadrangular membrane
 - Posteriorly by piriform sinus

Fig. 14-5. Coronal view of the larynx.

(Redrawn from Sobotta J: *Atlas der anatomie des menschen in 2 volumes*, ed 20, Munich, Germany, 1975, Urban & Fischer Verlag, Fig. 766.)

- Superiorly is in continuity with pre-epiglottic space
- Contains lymphatics and blood vessels but no lymph nodes
- Supraglottic tumors may spread into paraglottic space and reach the subglottis or extend beyond the limits of the larynx.
- Fixation of vocal cord represents good indicator of a tumor in the paraglottic space
- Subglottic space:
 - Bounded:
 - Laterally by conus elasticus (i.e., cricovocal membrane)
 - Medially by mucosa of subglottic region
 - Superiorly by undersurface of Broyle's ligament
 - Continuous with inner surface of cricoid cartilage and its mucosa
 - Broyle's ligament:
 - Site where vocal fold meets anteriorly (known as anterior commissure) and is region where fibers of vocal ligament pass through thyroid cartilage to blend with overlying perichondrium forming Broyle's ligament
 - Broyle's ligament contains blood vessels and lymphatics, representing potential route for escape of malignant tumors of the larynx.
 - Laryngeal cartilage (Fig. 14-6)
- Skeleton of larynx composed of cartilage, fibrous sheets, and bands; attached muscles adjust position of cartilages, changing shape and tension of vocal cords
- Thyroid cartilage:
 - Largest of the laryngeal cartilage
 - Double-winged

Fig. 14-6. Cartilage framework of the larynx.

(From Som HD, Curtin PM: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Figure 31-7, p 1909. Modified from www.netterimages.com.)

- Cricoid cartilage:
 - Only complete ring in respiratory system
 - Represents foundation of larynx
 - Resembles signet ring with larger part facing posteriorly
- Arytenoid cartilage:
 - Paired cartilage perched on superior edge of cricoid cartilage
 - Each cartilage is pyramidal.
 - At inferior aspect are two projections:
 - Muscular process on posterolateral margin
 - Vocal process located anteriorly
 - Vocal ligament attaches to vocal process of arytenoid cartilage.
 - Superior process represents apex of pyramid:
 - Corniculate cartilage rests on the margin of the superior process of the arytenoid cartilage.
 - Articulations between the various laryngeal joints are synovial and may be involved by an arthritic process.

Innervation

- Innervation of the larynx is by two sets of nerves, both branches of the tenth (vagus) nerve:
 - Superior laryngeal nerve:
 - Largely sensory
 - Inferior laryngeal nerve:
 - Largely motor supplying the intrinsic muscles of the larynx

Vascular Supply and Lymphatic Drainage

- Arteries and veins:
 - Arterial supply to the larynx consists of two pairs: superior and inferior laryngeal arteries derived from the superior and inferior thyroid arteries, which are branches of the carotid artery and the subclavian artery, respectively.
 - Superior and inferior laryngeal veins parallel the arteries.
- Lymphatics:
 - Divided into superior and inferior groups by the vocal fold:
 - Superior group drains to the upper portion of the deep cervical lymph nodes.
 - Inferior group drains to the lower deep cervical lymph nodes.

Histology (Figs. 14-7 through 14-11)

- Epiglottis and true vocal cord:
 - Lined by nonkeratinizing stratified squamous epithelium

Fig. 14-7. Glottic epithelium.

The “resting” epithelium of the glottic compartment (as well as the epiglottis) is nonkeratinizing squamous epithelium. The epithelium is relatively flat and matures toward the surface. The submucosa of the glottic region is devoid of seromucous glands and as compared with the other compartments of the larynx has fewer lymphovascular spaces.

- False vocal cord, ventricle, and subglottis:
 - Lined by pseudostratified ciliated respiratory epithelium
- Transitional-type epithelium is present between the ciliated respiratory epithelium of the supraglottis or subglottis and the squamous epithelium of the true vocal cord:
 - Squamous epithelial-ciliary respiratory epithelial junction
 - Transitional-type epithelium:
 - Appears abruptly
 - Is composed predominantly of basaloid or immature squamous cells with hypercellularity, disorganization, absence of maturation, and increased nuclear-to-cytoplasmic ratio
 - May be misdiagnosed on biopsy or by frozen section as severe dysplasia or carcinoma in situ (CIS) but in contrast to severe dysplasia/CIS the cells have vesicular nuclei, smooth nuclear contours, absence of significant pleomorphism, and absence of mitoses away from the basement membrane
- Seromucous glands found:
 - Lower two thirds of the epiglottis
 - Ventricular submucosa
 - Most abundant in false vocal cord
 - In subglottis
 - Absent in region of true vocal cord:
 - Glands present immediately above and below squamocolumnar junction

Fig. 14-8. Supra- and subglottic epithelium.

The “resting” epithelium of the supra- and subglottic region is pseudostratified ciliated respiratory epithelium. In contrast to the glottic region, the submucosa in the supra- and subglottic compartments includes submucosal seromucous glands.

- Laryngeal cartilage:
 - Epiglottis, cuneiform, and corniculate cartilages are elastic-type cartilage.
 - Thyroid, cricoid, and arytenoid cartilages are hyaline-type cartilage.
 - Hyaline cartilage components of the larynx may calcify and/or ossify with age:
 - Represents “normal” aging process in the larynx
 - If traumatized may result in a fractured larynx
 - Ossification/calcification of cartilage important to spread of laryngeal carcinoma:
 - Cartilage involved by carcinoma only when ossified
 - Chondrosarcomas frequently occur in cartilage that has ossified/calcified.
- Laryngeal saccule:
 - Pouch that ascends from anterior one third of ventricle between the false vocal cord and the inner surface of the thyroid cartilage in a vertical plane and ends as a blind sac

Fig. 14-9. Transitional epithelium.

A and B, Laryngeal transitional-type epithelium is present between the ciliated respiratory epithelium lining of the supraglottic and subglottic larynx, and the squamous epithelium of glottic larynx. The transitional-type epithelium is composed predominantly of basaloid or immature squamous cells with hypercellularity, disorganization, absence of maturation, and increased nuclear-to-cytoplasmic ratio. These overall features may be misdiagnosed as intraepithelial severe dysplasia or carcinoma in situ (CIS), but in contrast to severe dysplasia/CIS the cells have vesicular nuclei, smooth nuclear contours, absence of significant pleomorphism, and absence of mitoses away from the basement membrane.

- Conical and curved slightly backward
- In infants, saccule is lined by a papillary mucous membrane with associated prominent submucosal lymphoid aggregates and is relatively large.
- In adults, saccule is lined by respiratory epithelium and there is an absence of submucosal lymphoid aggregates.
- Orifice of the saccule at the ventricle is only 0.5 to 1.0 mm in diameter and can become obstructed by infections, tumors, trauma, fibrosis:
 - If there is distention of the saccule by air with an open communication with the laryngeal lumen this is termed a laryngocele.

Fig. 14-10. Mineralization of laryngeal cartilage.

With age, the hyaline cartilage of the thyroid, cricoid, and arytenoid cartilages may calcify and/or ossify. This “normal” aging phenomenon may fracture when traumatized and is considered an important pathway for spread of laryngeal carcinoma when involved by carcinoma.

- If there is distention of the saccule with accumulation of secretions, a cyst is formed and this is referred to as a saccular cyst.
- Vocal cord ligament
 - Lies deep to true vocal cord
 - Represents thickened elastic tissue lying under free edge of vocal cord
 - Inserts on thyroid cartilage anteriorly and vocal process of arytenoid cartilage posteriorly
 - Biopsies taken in this anatomic location may include the vocal cord ligament, which, if unrecognized, may be misdiagnosed as a myxoma or peripheral nerve sheath neoplasm.
- Reinke space:
 - Loose connective tissue within the lamina propria of true vocal cord lying between the vocal cord ligament and surface squamous epithelium
 - Contains capillaries but lacks lymphatics
 - Sparse numbers of seromucous glands
 - Common location for vocal cord polyps/nodules:
 - Accumulation of extracellular fluid (Reinke edema)
 - Persists owing to poor lymphatic drainage
 - May be initiated by vocal abuse
 - Carcinomas of this location tend to remain localized owing to limited vascular spaces.

Fig. 14-11. Vocal cord ligament.

The vocal cord ligament, a normal anatomic structure of the larynx representing thickened elastic tissue lying under the free edge of the vocal cord, lies deep to the true vocal cord. Biopsies taken in this anatomic location may include the vocal cord ligament, which, if unrecognized, may be misdiagnosed as a cartilaginous lesion, a myxoma, or a peripheral nerve sheath neoplasm.

HYPOPHARYNX

- As detailed in Section 3, hypopharynx to include the piriform sinus belongs to the pharynx and all details relative to the embryology, anatomy, and histology are provided in that section.

TRACHEA

Embryology

- Endodermal lining of the middle segment of the laryngotracheal tube gives rise to the epithelium and glands of the trachea.
- Cartilage, connective tissue, and muscle derive from surrounding splanchnic mesenchyme.

Anatomic Borders

- Extends from the lower border of the cricoid cartilage to the carina
- In adults, the trachea averages 11 cm in length and 20 to 27 mm transversely.
- There are a total of 18 to 22 tracheal rings with approximately two tracheal rings per centimeter of trachea.
- Superior border:
 - Continuous with the larynx
- Inferior border:
 - Continuous with the bronchi
- Anterior border:
 - Associated with the thyroid gland
- Posterior border:
 - Associated with the esophagus

Innervation

- Cervical portion of the trachea derived from the recurrent laryngeal nerve, which gives off branches to the trachea as it ascends to the larynx

Vascular Supply and Lymphatic Drainage

- Arterial:
 - Main supply by the inferior thyroid arteries

- Thoracic end supplied by the bronchial arteries, which give off branches to anastomose with the inferior thyroid arteries:
 - All of these vessels also supply the esophagus.
- Venous:
 - Veins end in the inferior thyroid venous plexus.
- Lymphatics:
 - Pretracheal and paratracheal lymph nodes
 - Anastomoses with the subcarinal, peribronchial, and esophageal lymph nodes

Histology

- Entire lining is ciliated respiratory epithelium.
- Abundant minor salivary glands (seromucous glands) located in lamina propria
- Cartilaginous rings are incomplete and form about two thirds of a circle:
 - Rings are connected to each other by a fibroelastic annular ligament.
 - Posterior (noncartilaginous) membranous part contains smooth muscle.

Non-Neoplastic Lesions of the Larynx and Trachea

CLASSIFICATION OF NON-NEOPLASTIC LESIONS OF THE LARYNX AND TRACHEA (Box 15-1)

BOX 15-1 Classification of Laryngeal and Tracheal Non-Neoplastic Lesions

- Vocal cord nodules/polyps
- Laryngocele and laryngeal cysts
- Contact ulcer
- Amyloidosis
- Subglottic stenosis
- Teflon granuloma
- Tracheopathia osteoplastica
- Infectious diseases
- Necrotizing sialometaplasia
- Radiation-induced changes
- Benign epithelial changes
- Others

ACQUIRED AND CONGENITAL LESIONS OF THE LARYNX AND TRACHEA

Vocal Cord Nodules and Polyps (Figs. 15-1 through 15-4)

Definition: Non-neoplastic stromal reactive process related to inflammation and/or trauma.

Synonyms: Screamer's, singer's, or preacher's nodules; corditis nodosa; diffuse polyposis (involvement of the entire vocal cord)

Clinical

- No gender predilection; may be seen in all age groups but most common from the third to sixth decades
- Clinicians distinguishing between nodules and polyps based on whether the lesion(s) is (are) sessile (nodule) or pedunculated (polyp)
- Regardless of terminology, the symptoms related to vocal cord polyps and nodules are similar and include hoarseness or voice changes ("breaking" of the voice).
- May be a single lesion arising from the true vocal cord or bilateral lesions involving the anterior or middle third of the true vocal cord:

- May occur anywhere along the vocal cord but most occur on the free edge at the junction of the anterior and middle thirds
- Point of maximal vibratory impact in the vocal cord is in the middle third of the true vocal cord (membranous cord), representing the most common site for polyps or nodules to occur.
- Follows voice abuse (phonatory trauma), infection (laryngitis), alcohol, smoking, or endocrine dysfunction (hypothyroidism):
 - Phonatory trauma is a central cause of nodule/polyp formation.
 - Infrequently, hypothyroidism may cause vocal cord edema, which may progress to formation of a myxoid polyp.
- *Helicobacter pylori* (HP), a common cause of gastritis and/or gastroesophageal reflux disease, may be associated with vocal fold minimal lesions (VFML) (e.g., polyps, nodules, contact ulcers):
 - HP can be detected by immunohistochemical staining or reverse transcriptase polymerase chain reaction (RT-PCR) in biopsies from patients with VFML.
 - Direct cause and effect between presence of HP and polyps/nodules not established
- Videostroboscopic examination of the glottal cycle is useful in the differential diagnosis of small lesions of the vocal fold cover that cannot be easily visualized:
 - An isolated lesion shows:
 - Irregular, incomplete closure
 - Reduced amplitude of vibration and mucosal wave on the vocal fold on the side of the lesion
 - Bilateral lesions of longer duration show:
 - Greater reduction in vibratory amplitude and mucosal wave due to increased submucosal fibrosis and perhaps presence of surface keratinization

Pathology

Gross

- Fusiform swelling, sessile, or pedunculated lesion(s) with a soft, rubbery, or firm consistency, white, tan, pearly, glistening, or red appearance measuring from a few millimeters up to 1 to 1.5 cm in greatest dimension

Fig. 15-1. Vocal cord polyps.

Endoscopic appearances of vocal cord polyp and nodules include (A) bilateral identical-appearing polypoid lesions, (B) large beefy-red, bilateral hemorrhagic polyps, (C) unilateral glistening (myxoid-appearing) polyp, (D) unilateral fibrotic polyp.

Histology

- Pathologic process occurs in Reinke's space, the area lying deep to the true vocal cord, which is essentially devoid of blood vessels and in response to injury has a tendency to accumulate fluid.
- Histologic subtypes include:
 - Edematous-myxoid:
 - Submucosal accumulation of pale blue to pink material admixed with a sparsely cellular and variably vascularized stroma
 - Fibrous:
 - Moderately cellular submucosa consisting of uniform oval to spindle-shaped cells associated with a varying amount of fibrous tissue deposition
 - Vascular:
 - Submucosa is marked by prominent dilated vascular spaces with or without associated hemorrhage.
 - Hyaline:
 - Dense eosinophilic submucosal deposition of fibrin material often closely apposed to vascular spaces
 - May suggest the presence of amyloid (Congo red staining is negative)
 - Mixed:
 - Combination of the above subtypes in a single lesion
- For all types the overlying epithelium may be atrophic, hyperplastic, and keratotic; rarely, dysplastic epithelium and/or invasive carcinoma may be identified.
- Histologic changes represent different tissue reactions to the initiating event and do not represent progressive (sequential) changes.
- Rarely, atypical stromal cells (i.e., myofibroblasts) similar to those seen in sinonasal inflammatory polyps may be present, which are:

Fig. 15-2. Histology of vocal cord polyps.

Histologic variants of vocal cord polyps/nodules include (**A, B**) vascular-hyaline type characterized by submucosal dilated vascular spaces and deposition of dense eosinophilic fibrin material closely apposed to vascular spaces; the hyaline subtype may be mistaken for amyloid deposition but stains for amyloid (e.g., Congo red) are negative; (**C**) fibrous type characterized by the presence of a moderately cellular submucosa consisting of uniform oval to spindle-shaped cells associated with a varying amount of fibrous tissue deposition;

Continued

Fig. 15-2, cont'd

(D) hemorrhagic type characterized by submucosal dilated vascular spaces with associated hemorrhage; (E, F) edematous-myxoid type characterized by submucosal accumulation of pale blue to pink material admixed with a sparsely cellular and sparsely vascularized stroma. Rarely, the myxoid type of vocal cord polyp may occur in association with hypothyroidism.

Fig. 15-3. Polyp with carcinoma.

Rare example of a (left) vascular-hyaline vocal cord polyp with associated (right) infiltrating squamous cell carcinoma.

Fig. 15-4. Atypical stromal cells.

Vocal cord polyp with associated atypical stromal cells (i.e., myofibroblasts). Similar to the atypical stromal cells in a sinonasal polyp, these cells in a vocal cord polyp are part of a reactive process (e.g., wound healing) and tend to cluster in proximity to vascular spaces.

- Characterized marked by nuclear enlargement and hyperchromasia
- Not associated with either increased mitotic activity nor a subepithelial condensation of stromal cells (“cambium layer”)
- Typically scattered in distribution over a wide area and do not appear concentrated in location or characterized by hypercellularity
- Histochemistry:
 - Negative staining for amyloid (Congo red, crystal violet, or thioflavin T stains)
- Cytogenetics and molecular genetics:
 - Messenger RNA genotypic profiles for extracellular matrix proteins, including procollagen I, collagenase, elastase, fibronectin, fibromodulin, decorin, hyaluronic acid synthase 2, and hyaluronidase correlated to a videostroboscopic parameter of mucosal wave stiffness showed:
 - Vocal cord polyps, characterized by stiffer mucosal waves, have higher levels of gene expression.
 - Reinke’s edema, characterized by stiffer mucosal wave scores, has lower gene activity levels.
- Generally, there is a good correlation between the clinical findings/diagnosis of vocal cord polyps/nodules and the histopathologic findings; however, except for cysts that are epithelial lined, there may be a lack of correlation between vocal fold lesions that may be clinically distinct (e.g., polyps, nodules, Reinke edema, others) and the histopathologic diagnosis/classification:
 - May be overlapping histologic finding including epithelial hyperplasia, basement membrane thickening, edema, vascular proliferation, and extracellular “amyloid-like” fibrin
 - No histologic feature that reliably distinguished among the lesions
 - In cases in which there may be a lack of correlation between the clinical diagnostic considerations and the histologic diagnosis, treatment should be individualized based on clinical judgment.
- Typically are not covered by surface epithelium as compared with polyps/nodules that typically include overlying surface (squamous) epithelium
- Amyloidosis:
 - Hyaline-type vocal cord nodule may be misinterpreted as amyloid deposition; however, staining for amyloid differentiates between these entities.
- Hemangioma
- Fibroma
- Neurofibroma:
 - Neurofibromas are S100 protein and Sox10 positive.
 - Vocal cord polyps/nodules S100 protein and Sox10 negative
- In rare examples showing atypical stromal cells the differential diagnosis may include a malignant neoplasm, including sarcoma (e.g., rhabdomyosarcoma) and carcinoma (e.g., spindle cell squamous carcinoma):
 - Laryngeal sarcomas are rare; the most common type of sarcoma of the larynx is a chondrosarcoma (see Chapter 16).
 - Atypical stromal cells in a polyp/nodule tend to be localized as compared with diffuse cellularity and nuclear atypia, including increased mitotic activity seen in association with a sarcoma.

Treatment and Prognosis

- Surgery:
 - Laser surgery can be used safely in the larynx to remove benign superficial laryngeal lesions.
- Voice therapy:
 - Postoperative voice therapy decreases the risk of recurrence.
- Vocal cord nodules/polyps can recur up to 5 years after diagnosis/therapy.

Laryngoceles (Figs. 15-5 through 15-9)

Definition: Abnormal dilatation of the saccule (appendix of the ventricle) containing air and maintaining an open communication with the laryngeal lumen.

Clinical

- No gender predilection; most common in the fifth through eighth decades of life:
 - May occur in pediatric ages
- Majority are unilateral but may be bilateral in up to 25% of patients.
- Three types of laryngoceles identified:
 - Internal laryngocoele: dilatation confined to the intrinsic larynx:
 - Reported incidence of 30%
 - External laryngocoele: dilated sac projects upward between the false vocal cord and the thyroid

Differential Diagnosis

- Myxoma:
 - True myxomas are rarely encountered in the larynx.
 - Typically occurs in supraglottic larynx rather than vocal cord (i.e., gottis) where polyps/nodules occur
 - Typically large (≥ 3 cm or larger) rather than small size of polyps/nodules
 - Tend to be avascular as compared with well-vascularized nature of polyps/nodules

Fig. 15-5. Large laryngocele.

The patient presented with a mass in the right neck. The large fluid-filled saccular cyst (L) fills the supraglottic paraglottic space and extends laterally into the neck. The position of the thyrohyoid membrane is indicated by the arrowhead. E, Epiglottis. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 31-111, p 1994.)

cartilage and laterally through the thyrohyoid ligament into the neck:

- Reported incidence of 26%
- Mixed (combined) laryngocele is a combination of internal and external laryngoceles:
 - Reported incidence of 44%
- Symptoms include:
 - Hoarseness, coughing, dyspnea, dysphagia, and sensations of foreign body or mass in the throat
 - External or mixed laryngoceles may present as:
 - Lateral neck mass that fluctuates with changes in intralaryngeal pressure and is compressible
 - Subcutaneous emphysema
 - Infected laryngoceles (laryngopyoceles) associated with pain and tenderness
- Diagnosis of laryngocele is a clinical one:
 - Despite clinical assurance of a diagnosis of a laryngocele, prudent therapy would include additional examination to rule out the presence of a neoplasm.
- Radiology:
 - Thin-walled air-filled cystic lesion communicating with laryngeal ventricle
 - CT (non-contrast-enhanced):
 - Internal laryngocele:
 - Low-density mass in supraglottic space

- Mixed laryngocele:
 - Low-density, thin-walled mass seen in the low submandibular space
 - Can be followed into larynx through thyrohyoid membrane
 - Internal component may be collapsed or dilated.
- Infected laryngoceles by contrast-enhanced CT have a thick, enhancing wall surrounding the laryngocele.
- Cause:
 - Laryngoceles can be congenital or acquired:
 - Acquired laryngoceles are related to occupation and include professions in which there is a tendency to excessively increase intralaryngeal pressures, which may result in the development of a laryngocele (e.g., glassblowers, musicians, and weight lifters).
 - Laryngoceles may have a coexistent (squamous cell) carcinoma:
 - Laryngoceles associated with carcinoma tend to be of the internal type.

Pathology

Gross

- Not as impressive as the clinical presentation; resected specimen is a smooth-surfaced, sac-like structure that may be devoid of fluid or if infected may contain pus.

Histology

- Respiratory epithelial-lined (ciliated, columnar) cyst with a fibrous wall
- Squamous metaplasia may be seen focally or, if infected, may completely replace the respiratory epithelium; in the presence of infection, a chronic inflammatory cell infiltrate may be seen in the wall of the cyst.
- Oncocytic metaplasia of the lining epithelium or minor salivary glands may be seen.

Differential Diagnosis

- Branchial cleft cyst
- Oncocytic papillary cystadenoma
- Laryngeal cysts:
 - Ductal cysts and saccular cysts (see below)

Treatment

- Asymptomatic cases require no treatment.
- Surgery may be necessary in those cases that become large and symptomatic.
 - Microlaryngoscopy involving use of CO₂ laser has become the main therapeutic procedure for the treatment of internal laryngoceles.

Fig. 15-6. Bilateral air-filled laryngoceles (axial CT).

A, The laryngoceles (*L*) are bilateral. On the left, there is extension between the hyoid bone and the thyroid cartilage into the lateral soft tissues (*arrow*). This is a combined internal/external laryngocele. Hyoid bone (*H*). **B**, Slightly caudad slice shows the bulge of the mucosa (*arrowhead*) at the supraglottic level. Laryngocele (*L*); intact contiguous paraglottic and preepiglottic fat (*arrow*). **C**, Caudad to **B**. The laryngocele (*L*) can be followed anteriorly (*arrow*) as the dilated appendix approaches the ventricle. **D**, The true cord level of the TAM (*arrow*) is identified. Note the crease of fat (*arrowhead*) along the lateral aspect of the muscle, representing the inferior extent of the paraglottic fat. The fat is normal. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 31-110, p 1993.)

- An external approach is main therapeutic approach for the treatment of combined laryngocele.
- Complications associated with laryngoceles include airway obstruction and infection (laryngopyocele):
 - For laryngopyoceles the initial treatment is by incision and drainage followed by antibiotic therapy and then surgical excision after the infection has been controlled.
- Rare complications include vocal cord paralysis and death due to asphyxia.

Laryngeal Cysts (Figs. 15-10 through 15-13)

Definition: Obstruction of the orifice of the laryngeal saccule or obstruction of the mucous gland ducts of the laryngeal saccule with subsequent accumulation of secretions resulting in cyst formation.

Fig. 15-7. Laryngocele.

Clinically, this laryngocele resulted in a large neck mass seen as a subcutaneous bulging mass at surgery.

Fig. 15-8. Excised laryngocele.

Resected laryngocele appearing as a smooth-walled cystic structure that contained clear fluid.

Synonyms: Saccular cyst; ductal cyst; oncocytic cyst; epithelial cyst

Classification

- Laryngeal cysts have been divided into two categories:
 - Ductal cysts:
 - Due to obstruction of the mucous gland ducts
 - Represent 75% of all laryngeal cysts
 - Saccular cysts:
 - Due to obstruction of the orifice of the laryngeal sacculi
 - Represent 25% of all laryngeal cysts

Fig. 15-9. Histology of laryngocele.

The histology of laryngocele is less dramatic than its clinical presentation and is characterized by the presence of a cystic lesion that may be lined by a varying cell types including respiratory (ciliated or columnar), squamous, and oncocytic epithelium. The cyst has focally fibrotic and hemorrhagic wall.

Clinical

- No gender predilection; occur over a wide age range but tend to be most common in individuals older than the sixth decade of life
 - May occur in pediatric ages
- Majority of cysts occur in the supraglottic larynx; less frequently, glottic and subglottic cysts occur.
 - Ductal cysts:
 - Majority occurs in the area of the true vocal cords but not in the region of the free margin, which lacks glands.
 - Next most common site is epiglottis
 - Less frequent sites include false vocal cords, ventricles, aryepiglottic folds, arytenoids, piriform sinus, anterior commissure, and subglottis.
 - Saccular cysts:
 - Occur in the supraglottic larynx:
 - Majority occurs in the region of the ventricles
 - Less often occur in the region of the aryepiglottic folds, lateral larynx
 - Saccular cysts can be further subdivided into anterior and lateral cysts, depending on the location, level of obstruction, and length of the sacculi:
 - Anterior:
 - Develop near the orifice of the ventricle overhanging the anterior glottis
 - Represent the majority of cases

Fig. 15-10. Axial CT of a laryngocele (saccular cyst).

A, There is an internal (*arrow*) and an external (*white arrowhead*) component. The position of the thyrohyoid membrane is signified by black arrowheads. A small air-filled external laryngocele (*L*) is seen on the opposite side. **B**, Lower scan through the supraglottic larynx shows the abnormality in the paraglottic space (*arrow*) and the external component (*arrowhead*). (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 1994, Elsevier, Fig. 31-113.)

Fig. 15-11. Tonsillar-type cyst.

A, Laryngeal tonsillar-type cyst showing the presence of a submucosal epithelial lined cyst (*arrowhead*) with lymphoid follicles and germinal centers in the cyst wall and an intact surface squamous epithelium (*arrow*). **B**, At higher magnification the cyst is lined by reticulated appearing epithelium infiltrated by type lymphocytes and plasma cells. These overall histologic features resemble palatine tonsillar crypt.

– Lateral:

- Bulge into the aryepiglottic folds, false vocal cords, or epiglottis
- Rarely present as a neck mass with the cyst extending through the thyrohyoid membrane.
- Other cysts types include tonsillar-type, epithelial, and oncocytic (require histologic confirmation—see below):
 - Tonsillar-type cyst:
 - Occurs primarily in the epiglottis, vallecula, or piriform sinus

Fig. 15-12. Laryngeal cyst.

A, Laryngeal epithelial-type cyst showing the presence of a submucosal epithelial-lined cyst (*arrow*) and an intact surface squamous epithelium (*arrowhead*). **B**, At higher magnification the cyst is lined by flattened (attenuated) epithelium (*arrow*) located within the submucosa subjacent to surface squamous epithelium (*arrowhead*). The cyst content includes acellular mucinous-appearing debris.

- Epithelial cyst:
 - Occurs primarily in the piriform sinus or vallecula
- Oncocytic cyst:
 - Occurs primarily in the false vocal cords and ventricles
- In general, laryngeal cysts may be solitary or multiple.
- Symptoms include:
 - Asymptomatic and identified incidentally
 - Hoarseness, coughing, dyspnea, dysphagia, sensation of foreign body in the throat, neck mass, pain
 - Infants may present with feeding problems.

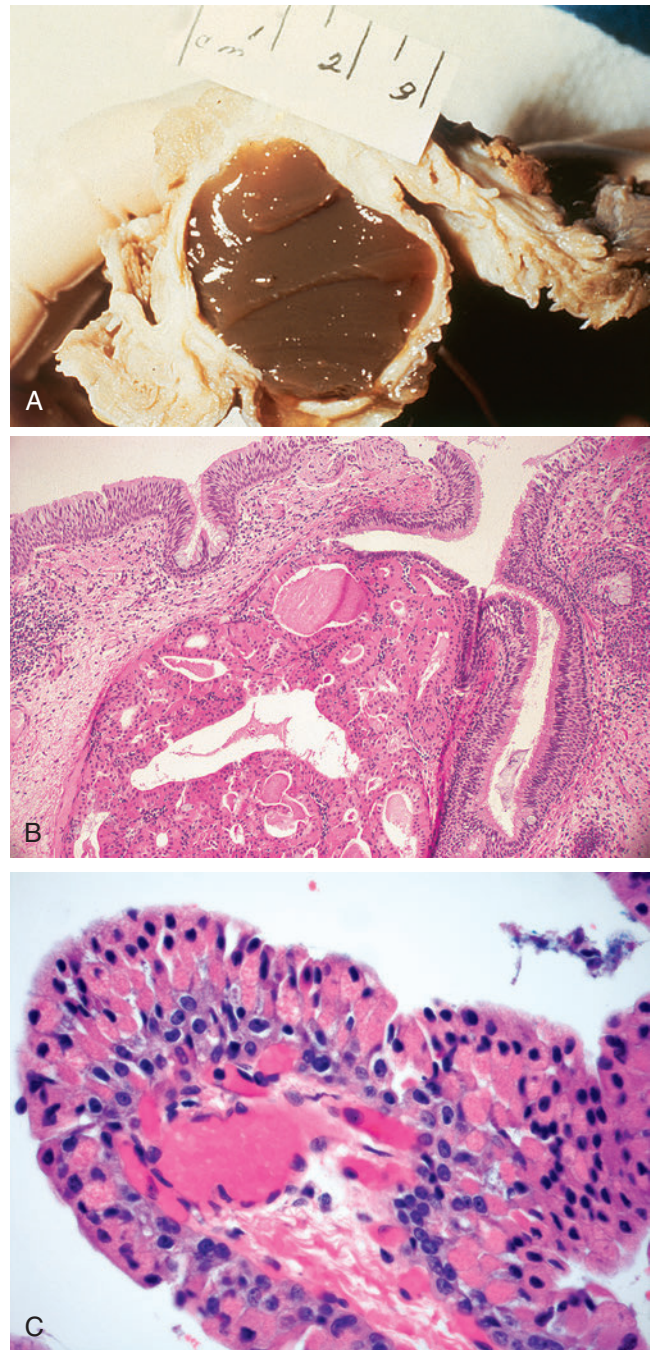

Fig. 15-13. Papillary oncocytic cyst.

A, Resected laryngeal oncocytic cyst characterized by its brown appearance. **B**, Histologically, the cystic proliferation is submucosal and cyst formation with (**C**) papillary architecture and cells with oncocytic cytoplasmic change. Depending on the presence of various structures, these cysts have also been referred to as oncocytic papillary cysts or oncocytic papillary cystadenomas.

- Radiology:
 - Fluid-filled cystic lesion in supraglottic larynx
- Cause:
 - Laryngeal cysts can be congenital or acquired:
 - Supraglottic cysts are due to obstruction of the orifice of the laryngeal saccule or obstruction of the mucous gland ducts of the laryngeal saccule with subsequent accumulation of secretions.
 - Glottic cysts may be due to vocal cord abuse.
 - Subglottic cysts may occur after intubation.
 - Congenital cysts may associated with other congenital or developmental abnormalities, including:
 - Down syndrome, cystic fibrosis, cardiac anomalies, laryngomalacia, conductive hearing loss, hydrocephalus, microcephalus, micrognathia, others

Pathology

Gross

- Ductal cysts:
 - Usually measure less than 1 cm in diameter
 - Tend to be superficial
- Saccular cyst:
 - Submucosal range in size from 1 to more than 7 cm in greatest dimension.

Histology

- Ductal and saccular cysts are lined by respiratory or squamous epithelium:
 - Histologic differentiation of ductal from saccular cysts is not possible, and this differentiation rests on clinical parameters.
 - Cyst may be lined by an oncocytic epithelium.
- Other histologic cyst types include:
 - Tonsillar type cyst:
 - Resembles palatine tonsillar crypt
 - Lined by stratified squamous and/or reticulated epithelium
 - Keratin-filled lumen
 - Lymphoid follicles with germinal centers seen in cyst wall
 - Epithelial cyst:
 - Lined by respiratory and/or squamous epithelium or an flattened (attenuated) epithelium
 - Epithelial lining may be papillary in architecture.
 - May contain keratin or mucin
 - May have lymphoid component in cyst wall
 - Oncocytic cyst:
 - Lined by oncocytic epithelium
 - May have prominent papillary architecture and referred to as oncocytic papillary cyst or oncocytic papillary cystadenoma

- Aside from the above, oncocytic metaplasia and hyperplasia can be seen in association with other laryngeal lesions, and these changes most likely represent an aging (metaplastic) phenomenon.

Differential Diagnosis

- Branchial cleft cyst
- Laryngocele

Treatment

- Conservative management is often advocated to include needle aspiration, deroofing of the cyst, laser marsupialization, or endoscopic removal:
 - Especially for infants and children to avoid stenosis
- Smaller anterior saccular cysts can be managed by endoscopic excision.
- Saccular cysts can be managed endoscopically in many cases, but if persistent after two or three endoscopic procedures, a prolonged course can be anticipated.
- Larger saccular cysts tend to recur repeatedly.
- Complete excision, endoscopically or through an external surgical approach, may shorten the clinical course.
- Tracheotomy may be required, some under emergent conditions.

Contact Ulcers of the Larynx

(Figs. 15-14 and 15-15)

Definition: Benign, tumor-like condition occurring most commonly along the posterior aspect of one or both vocal cords.

NOTE: Although termed as an ulcerative process, not infrequently due to chronicity of disease areas of the lesion may be ulcerated and other areas may show epithelial hyperplasia, the latter a reactive/regenerative process.

Synonyms: Pyogenic granuloma of the larynx; intubation granuloma

Clinical

- More common in men than women; occur over a wide age range:
 - Generally seen in the adult population
 - Uncommon in children but not restricted to any specific age group
- Most common site of occurrence is along the posterior aspect of one or both vocal cords primarily in the area of the vocal cord process of the arytenoid cartilage:
 - Propensity for contact ulcers to occur along the posterior vocal cords includes:

Fig. 15-14. Laryngeal contact ulcers.

Contact ulcers of the larynx (CUL) appearing as **(A)** bilateral polypoid and focally ulcerated, tan-white masses; **(B)** bilateral polypoid beefy red masses; **(C)** unilateral friable polypoid proliferation; and **(D)** large mass filling and obstructing the airway. All of these lesions developed after intubation.

- Posterior vocal cord experiences the greatest excursion during opening and closing of the glottis.
- Mucoperichondrium overlying the posterior vocal cord is extremely thin and more susceptible to injury.
- Additionally, the subepithelial connective tissue in this area is relatively sparse.
- Although the majority occurs along the posterior vocal cords, other vocal cord sites may be affected.
- Symptoms include:
 - Hoarseness most common
 - Less commonly, may include dysphagia, sore throat, dysphonia, difficulty breathing, choking, foreign body sensation in the throat, and pain
 - Duration of symptoms may be from weeks to years.
- Etiologic factors include:
 - Gastroesophageal reflux disease (GERD) with acid regurgitation
 - Not infrequently patients may be unaware of their condition and while supine during sleep the refluxed acid injures the posterior cord resulting in contact ulcer
 - Tends to be more common in men

Fig. 15-15. The histology of CUL.

A, Polypoid, ulcerated lesion with associated granulation tissue and inflammation. Note the linear perpendicular orientation of the superficial blood vessels to the surface, a feature often seen in association with reactive processes. **B**, Often CULs are recurrent (chronic) lesions resulting in a combination of concurrent ulceration (active disease) and hyperplastic squamous epithelium (reactive/healing process). **C**, Active lesions show ulceration with associated fibrinoid necrosis and the presence of subjacent scattered multinucleated giant cells and granulation tissue. **D**, Within the granulation tissue component dilated blood-filled vascular spaces may be seen, simulating the appearance of a vascular neoplasm.

- *Helicobacter pylori* (HP) may be detected by immunohistochemical staining or reverse transcriptase polymerase chain reaction (RT-PCR):
 - HP also may be identified in oral cavity, sino-nasal tract, pharynx, and middle ear mucosa.
 - Direct cause and effect between HP and development of contact ulcer and/or other upper aerodigestive tract lesions (non-neoplastic and neoplastic) not established
- Vocal abuse:
 - Shouting, persistent coughing, or throat clearing
 - Tends to be more common in men
- Postintubational trauma:
 - Postintubational contact ulcers tend to occur more frequently in women as a result of the smaller luminal diameter seen in women.
- Lesions may not become manifest until weeks to months after intubation injury.

Pathology

Gross

- Ulcerated, polypoid, nodular, or fungating mass with a beefy red to tan-white appearance ranging in size up to 3 cm in diameter

Histology

- Most often includes presence of an ulcerated lesion with associated fibrinoid necrosis, granulation tissue, and acute and chronic inflammation; additional associated findings may include:
 - Scattered multinucleated giant cells especially lying just below the ulceration:
 - Well-formed granulomas are not a feature.

- Marked vascular proliferation:
 - May be proliferative/exuberant, suggesting a vascular neoplasm (e.g., hemangioma), which are rare in the larynx
 - Papillary endothelial hyperplasia may be present.
- Reactive spindle cells (myofibroblastic) proliferation:
 - May be bizarre appearing with enlarged hyperchromatic nuclei but ample amount of fibrillar-appearing cytoplasm present (low nuclear-to-cytoplasmic ratio)
 - May include increased mitotic activity but atypical mitoses not present
- As a result of recurrent (chronic) disease reactive changes including epithelial hyperplasia may be present:
 - May occur concurrently with surface ulceration
 - May occur in the absence of an ulcerative component
- Histochemistry:
 - Special stains for microorganisms are negative.
- Immunohistochemistry:
 - Generally of limited utility
 - Reactive myofibroblasts variably reactive for actins (muscle-specific, smooth muscle) and desmin but typically negative for cytokeratins and/or p63

Differential Diagnosis

- Infectious disease(s)
- Squamous carcinoma and variants thereof especially spindle cell squamous carcinoma:
 - Squamous cell carcinoma occurring in the posterior vocal cord area is decidedly uncommon.
- Inflammatory myofibroblastic tumor (see Chapter 16)
- Vascular neoplasms:
 - Lobular capillary hemangioma
 - Angiosarcoma
 - Kaposi sarcoma

Treatment

- Identify and direct treatment to the underlying cause:
 - Medical therapy for GERD, including proton-pump inhibitor therapy
 - Voice therapy for voice abuse
- Persistence and recurrences are common:
 - Awareness that this is a specific clinicopathologic entity results in a definitive diagnosis rather than a descriptive histopathologic diagnosis.
 - A descriptive diagnosis, although not technically incorrect, may not suggest that the lesion is usually caused by an extralaryngeal process that requires therapy.

- Failure to suggest a diagnosis of contact ulcer may result in delay in appropriate curative therapy, thereby resulting in persistence and recurrence of disease.

Amyloidosis (Figs. 15-16 and 15-17)

Definition: Protein misfolding disease characterized by extracellular accumulation of fibrillar proteins (amyloid)

Fig. 15-16. Amyloidosis.

A, Laryngeal amyloidosis as seen by the presence of mucosal covered, diffuse swelling in the glottic and subglottic region. **B**, Lingual amyloidosis resulting in macroglossia.

Fig. 15-17. Amyloidosis.

A, The histologic appearance of amyloid includes deposition of eosinophilic, acellular, amorphous, somewhat nodular material throughout the submucosa including around vascular spaces; **B**, Congo red staining for amyloid showing characteristic apple-green birefringence.

identified in association with a variety of clinical settings and occurring in a variety of tissue sites.

- Amyloidosis is the name for 30 protein-folding diseases characterized by extracellular deposition of a specific soluble precursor protein that aggregates in the form of insoluble fibrils:
 - Rigid and unbranching fibrils approximately 10 nm in diameter characterized by a molecular beta-pleated sheet structure that is usually composed of peptides arranged in an antiparallel configuration
 - Structure of the fibrils is responsible for its insolubility, resistance to proteolysis, and binding affinity for Congo red dye that shows a characteristic green birefringence when viewed under polarized light.
 - Extracellular deposition of amyloid fibrils in organs and tissues results in tissue infiltration and swelling, leading to progressive loss of function of the affected organ.

Clinical

- Classification of amyloidosis includes:
 - Primary systemic amyloidosis:
 - Defined as not being associated with an underlying chronic disease
 - Amyloid deposition present in a variety of viscera including heart, gastrointestinal tract, tongue, others
 - Chemical composition: IgG light chain (kappa or lambda) origin (AL)
 - Myeloma-associated amyloidosis:
 - Chemical composition: IgG light chain (kappa or lambda) origin (AL)
 - Localized (solitary) amyloidosis:
 - Chemical composition: IgG light chain (kappa or lambda) origin (AL)
 - Secondary (systemic) amyloidosis:
 - Defined as being associated with an underlying chronic disease and with amyloid deposition in the kidneys, adrenal glands, liver, and spleen
 - Chemical composition: serum amyloid A (SAA)
 - Familial Mediterranean fever:
 - Chemical composition: serum amyloid A (SAA)
 - Familial amyloidosis:
 - Chemical composition: transthyretin (TTR; prealbumin)
 - Senile amyloidosis:
 - Chemical composition: transthyretin (TTR; prealbumin)
 - Dialysis-associated amyloidosis:
 - Chemical composition: β_2 -microglobulin (β_2M)
- In head and neck, amyloid generally is localized or solitary in form.
- Amyloidosis can affect almost every head and neck site but the most common sites of occurrence include the larynx and tongue:
 - Other sites of involvement may include nasopharynx, sinonasal tract, hypopharynx, trachea, external and middle ear, others.

Laryngeal Amyloidosis

- Most often is localized (solitary) and rarely part of systemic disease:
 - Laryngeal amyloidosis is generally a solitary lesion.
 - In up to 15% of patients amyloid deposition may occur in other head and neck sites (trachea, bronchus, tongue).
 - Rarely may be associated with primary or secondary amyloidosis:
 - Diagnosis of laryngeal amyloidosis should prompt clinical evaluation to exclude the

presence of primary or secondary amyloidosis, including:

- Serum and urine electrophoresis
- Immunoelectrophoresis
- Needle aspirate of abdomen to evaluate for the presence of amyloid, which would be positive in up to 95% of patients with primary (systemic) amyloidosis and approximately two thirds of patients with secondary (systemic) amyloidosis
- No gender predilection; may occur over a wide age range but most patients present in the fifth through seventh decades of life
- Most common complaint is hoarseness; other symptoms include dyspnea and cough.
- Can affect any portion of the larynx but most frequently seen along the true vocal cords, false vocal cords, and ventricle
- May be nodular or diffuse; single or multiple deposits
- May be associated with laryngocele

Lingual Amyloidosis

- In contrast to laryngeal amyloidosis, lingual amyloidosis is frequently a target organ as part of primary (systemic) amyloidosis:
 - Diagnosis of lingual amyloidosis should prompt clinical evaluation for systemic amyloidosis.
 - Approximately 15% of patients with primary (systemic) amyloidosis have underlying multiple myeloma.
- More common in men than in women; occurs over a wide age range with median age in the seventh decade of life
- Marked enlargement of the tongue (macroglossia) occurs in a minority of cases:
 - Tongue may protrude from the mouth, interfering with chewing, swallowing, and speaking.
 - Tongue appears pale gray to red, is firm, and may be painful.

Pathology

Gross

- Mucosal covered, firm, tan-yellow to gray that tends to appear as a polypoid mass when involving the glottis and supraglottis or as diffuse swelling when involving the subglottis.

Histology

- Extracellular eosinophilic, acellular, amorphous material deposited randomly throughout the submucosa and generally does not alter the appearance of the surface epithelium

- The deposition is often seen around blood vessels (“angiocentric”) or within the walls of vascular spaces without producing vascular compromise.
- Submucosal deposition of amyloid results in the disappearance of the seromucous glands.
- An associated chronic inflammatory infiltrate including plasma cells, lymphocytes, and histiocytes may be seen and often a foreign body type giant cell reaction is identified.
- Histochemistry:
 - Stains for amyloid (Congo red, crystal violet, thioflavin T) are positive.
 - Apple-green birefringence is seen under polarized light with Congo red staining.
- Immunohistochemistry:
 - Laryngeal amyloid is of light chain origin (AL):
 - Lambda light chain greater than kappa light chain
 - Negative for amyloid A protein, transthyretin (prealbumin), and B₂-microglobulin
 - Plasma cells are polyclonal.
- Electron microscopy:
 - Linear nonbranching fibrils varying in size from 50 to 150 Å in diameter, 7.5 to 10 nm in width
 - B-pleated sheet configuration

Differential Diagnosis

- Vocal cord nodules/polyps of the hyalinized type
- Lipoid proteinosis (hyalinosis cutis et mucosae):
 - Familial disorder possibly associated with autosomal recessive inheritance characterized by amorphous deposits of lipoprotein primarily in the skin and mucous membranes
 - Also known as Urbach-Wiethe disease
 - Clinical features include skin lesions, beady deposits under the eyelid margins, and intracranial (hippocampal gyrus) calcifications as seen by radiography.
 - Localized laryngeal involvement may occur, but more often widespread involvement is seen including the oral cavity and oropharynx.
 - Involvement of the larynx results in hoarseness or an abnormal cry (a common sign in infancy); dysphagia may also occur.
 - Multinodular growths may be seen in the laryngeal mucosa, which appear as a diffuse deposition of hyaline-like material in submucosal tissues by light microscopy.
 - Neutral and acid mucopolysaccharides can be demonstrated by special stains; amyloid stains are negative.
 - Endoscopic removal or tracheostomy may be necessary in cases attaining a large size, causing airway obstruction.

Treatment and Prognosis

Localized Amyloidosis

- Local endoscopic resection is usually curative.
- Persistent or recurrent local disease may occur and usually does so within 5 years of the initial treatment.

Systemic Amyloidosis

- Treatment is directed at limiting amyloid deposition by suppressing clonal proliferation of protein-producing cells:
 - Precursor-product concept is current basis of treatment aiming to decrease levels of precursor proteins in serum to normal or undetectable values, thereby stopping further growth of amyloid deposits:
 - Treatment for SAA is by complete suppression or eradication of the underlying chronic inflammatory disease.
 - Treatment for AL amyloidosis aimed at eradicating the underlying plasma cell dyscrasia by chemotherapy and returning the abnormally increased level of kappa or lambda free light chain in the blood to the normal range
 - Treatment for patients with hereditary ATTR amyloidosis has been liver transplantation with aim of removing source of 99% of the mutated TTR in the circulation:
 - Not always successful because ATTR amyloid sometimes progresses in the heart after liver transplantation
 - Treatment for patients with dialysis-associated amyloidosis is renal transplantation:
 - Amyloidosis seems to stabilize.
 - β_2 M serum levels decrease to normal.
 - Bone pain and stiffness decrease.
 - Cystic lesions do not increase further in size.
 - However, regression of amyloid deposits not reported
- Prognosis depends on the severity of organ involvement:
 - Median survival in patients with primary (systemic) amyloidosis is 1 to 2 years.
 - Survival rates are less in patients with multiple myeloma.
- Death is due to:
 - Organ failure (cardiac or renal)
 - Complications of multiple myeloma

Subglottic Stenosis (SS)

(Figs. 15-18 and 15-19)

Definition: Congenital or acquired, partial or complete narrowing of the laryngeal lumen.

Synonyms: Laryngotracheal stenosis; tracheal stenosis

Clinical

- Relatively rare condition with acquired stenosis more common than congenital stenosis
- No gender predilection; affects all age groups:
 - Idiopathic SS is more common in women than in men.
- Symptoms relate to airway obstruction and include:
 - Progressive respiratory difficulty, biphasic stridor, dyspnea, and air hunger
 - Other symptoms include hoarseness, abnormal cry, aphonia, dysphagia, and feeding abnormalities.
- In congenital stenosis, symptoms appear at or shortly after birth:
 - Congenital stenosis is the third most common laryngeal congenital disorder preceded by laryngomalacia and recurrent laryngeal nerve paralysis.
- In acquired stenosis, usually there is a history of trauma followed by a latent period of 1 month or longer prior to the manifestations of symptoms:
- Cause of acquired SS includes:
 - Trauma is most common cause:
 - Blunt or penetrating trauma, prolonged endotracheal intubation, endotracheal burns, post-surgical, postradiotherapy
 - Neoplasms (carcinoma, cartilaginous, fibrous and hematolymphoid [e.g., MALT lymphoma] neoplasms)
 - Infectious and/or inflammatory diseases:
 - Tuberculosis, syphilis, sarcoidosis, lupus erythematosus, granulomatosis with polyangiitis (formerly referred to as Wegener granulomatosis), relapsing polychondritis, amyloidosis
 - Laryngeal granulomatosis with polyangiitis:
 - Occurs much more frequently in women
 - Generally affects the larynx only when the disease already affects other more common sites (sinonasal tract, lungs, genitourinary system)
 - In active disease, elevated serum levels of antineutrophil cytoplasmic antibodies (C-ANCA) and proteinase 3
 - Even in absence of elevated ANCA levels, in presence of supporting histologic findings (e.g., geographic ischemic-type necrosis, vasculitis, mixed chronic inflammation, scattered multinucleated giant cells) diagnosis cannot be excluded
 - Chemical exposure
 - Idiopathic

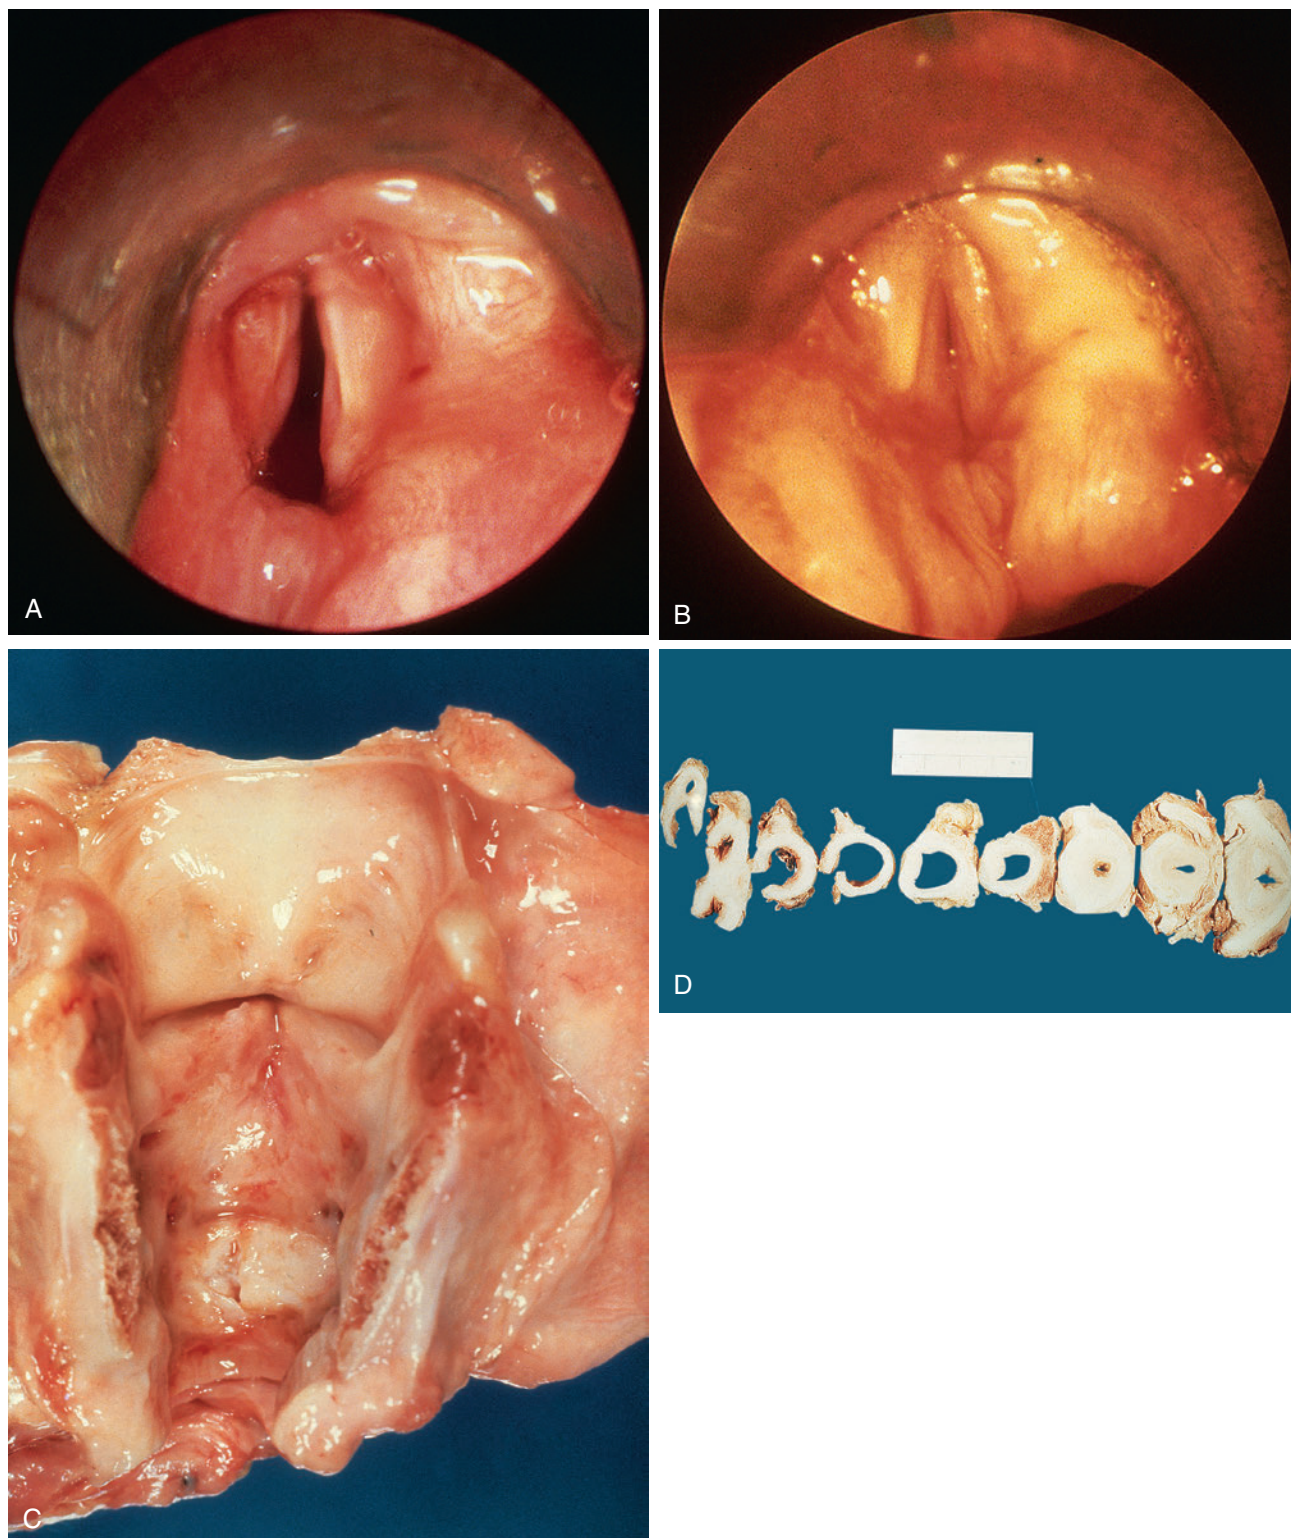

Fig. 15-18. Subglottic stenosis.

Subglottic stenosis resulting in (A) partial narrowing of the endolaryngeal luminal diameter; (B) complete narrowing of the endolaryngeal lumen; (C) laryngectomy in which a tan-white mass bulging into the endolaryngeal lumen at the lower subglottic region is identified; (D) resection specimen showing progressive narrowing (*left to right*) of the endolaryngeal lumen.

Fig. 15-19. Histology of SS.

Despite the impressive clinical picture of subglottic stenosis, the histology is remarkably bland as seen by the presence of a variably cellular fibroblastic proliferation with associated collagenized stroma.

- In children and adults, trauma is most common cause of stenosis.
- Complete physical evaluation of the entire upper aerodigestive tract is indicated to rule out separate congenital anomalies or other acquired injuries:
 - Concomitant pseudotumor of the orbit may occur in association with idiopathic subglottic stenosis.
 - Both lesions display identical histologic features.

Pathology

Gross

- Partial or complete narrowing of the endolaryngeal luminal diameter:
 - Tendency for process to be circumferential
 - Stenosis tends to begin just below the true vocal cord with progressive narrowing toward the cricoid cartilage.
 - Maximum stenosis tends to occur at the level of the cricoid cartilage and upper trachea.
- Depending on the cause a mucosal or submucosal mass or submucosal bulging may be seen.

Histology

- Histologic picture dependent on the cause of the stenosis:
 - In idiopathic stenosis:
 - Submucosal fibrous proliferation with associated nonspecific chronic inflammation
 - Fibrosis tends to be dense (keloid type) and hypocellular.
 - Cellular component includes spindle-shaped fibroblasts.
 - Variable chronic inflammatory cell infiltrate is present.
 - Overlying epithelium unchanged or may show squamous metaplasia
 - Histologic picture is similar to that of fibromatosis identified in the sinonasal tract and may, in fact, represent the same pathologic process.
 - Infections:
 - Granulomatous inflammation may be present.
 - Microorganisms may be identified.
 - Sarcoidosis:
 - Noncaseating granulomatous inflammation

Differential Diagnosis

- Infectious disease(s)
- Collagen vascular disease(s)
- Neoplasms

Treatment and Prognosis

- Treatment is based on the age of the patient, degree of stenosis, and underlying pathology.
- In general, cases of acquired stenosis initially require tracheotomy to establish an airway followed by endoscopic dilatation, laser excision, or external surgical (open excision with reconstruction) management.
- Prognosis is dependent on multiple factors with the etiology probably the most important:
 - Congenital subglottic stenosis is less severe than acquired types and many patients outgrow their condition, making surgical reconstruction often unnecessary with management by conservative methods.
- Subglottic stenosis remains a treatment challenge:
 - Patients often symptomatically improved after endoscopic dilation but recurrence rates remain high.

Teflon Granuloma

(Figs. 15-20 through 15-22)

Definition: Foreign body granulomatous reaction to extravasation of injected Teflon used in the treatment of vocal cord paralysis.

Synonym: Teflonoma

Fig. 15-20. Aspirated foreign material.

Fine-needle aspiration biopsy of a neck mass in a patient with past history of Teflon injection shows the presence of giant cells with associated glassy-appearing foreign material.

- Intracordal fluorocarbon (Teflon; polytef) injection has been used for decades to correct paralytic dysphonia, a result of unilateral laryngeal paralysis.
- Vocal cord paralysis, treated by Teflon injection, may be caused by primary laryngeal carcinoma or metastatic carcinoma (e.g., breast, lung) involving the recurrent laryngeal nerve, surgical trauma to the recurrent laryngeal nerve, or postviral neuritis.
- Cord paralysis may result in aspiration problems secondary to open glottic incompetence during deglutition, an ineffective cough, and poor voice production.
- To correct these deficits and restore glottic competence intracordal injection of Teflon paste is used as the preferred treatment.
- Injection of Teflon paste into the vocal cord causes a localized foreign body reaction walled off by surrounding fibrosis:
 - Teflon swells the paralyzed vocal cord and brings it nearer to the midline so that the functioning vocal cord can more easily approximate it and effectively close the glottis, thereby alleviating the resulting symptoms.
- Infrequently, Teflon extravasates and infiltrates into the soft tissues of the neck and larynx; depending on the error, Teflon paste:
 - May be deposited through the cricothyroid space and outside the larynx, resulting in a neck mass
 - Be placed between the mucosa and the conus elasticus causing a subglottic bulge
 - May infiltrate into the vocalis portion of the medial thyroarytenoideus muscle, causing immobilization of this area rather than medial displacement of the vocal cord

Fig. 15-21. Histology of Teflon granuloma.

The histologic features of Teflon granuloma include (A) submucosal deposition/accumulation of foreign (glassy appearing) material in the vocal cord; (B) associated foreign-body giant cell reaction; (C) extension to the soft tissues (i.e., skeletal muscle) of the neck region (*left*).

- Resulting iatrogenically induced mass may clinically be mistaken for a neoplastic process.

Clinical

- Use of Teflon to correct vocal cord paralysis is generally limited to the adult population; therefore the

Fig. 15-22. Properties of Teflon.

The Teflon material is (A) birefringent under polarized light; (B) appears “flake-like” by scanning electron microscopy; (C) virtually entirely of fluorocarbon derivation as determined by infrared absorptive spectrophotometry (IAS), and (D) unequivocally identified by the presence of a major peak for fluorine at 0.68 keV by energy-dispersive x-ray analysis (EDXA).

development of a “teflonoma” is almost always seen in adults.

- No gender predilection
- Symptoms related to extravasation of the Teflon include a neck mass, airway obstruction, or persistent hoarseness:
 - Symptoms may manifest from as short as a month after injection to as late as many years (decade or more) after injection.
- Positron emission tomography with ^{18}F -fluorodeoxyglucose (^{18}F FDG) may show increased (false-positive) uptake, suggesting the presence of a malignant neoplasm.

Pathology

Gross

- In the larynx, tumors may appear as polypoid lesions within the submucosal compartment of the vocal

cord area or may be well-delineated, firm masses when identified in the soft tissues of the neck.

- Lesions vary from a few millimeters to 2 cm.

Fine-Needle Aspiration Biopsy

- Diagnosis can be made by fine-needle aspiration smears, which show clusters of giant cells with associated glassy-appearing foreign material.

Histology

- Submucosal or soft tissue foreign body giant cell reaction
- In vocal cord region:
 - Foreign body giant cell reaction is submucosal with extension to underlying muscle and cartilage.

- In neck:
 - Foreign body reaction can infiltrate into all soft tissue structures, including skeletal muscle, and can involve the thyroid gland.
- A glassy-appearing material is seen within the multinucleated giant cells:
 - Material is birefringent under polarized light.
- Special analysis
 - Adjuncts to conventional light microscopic analysis include evaluation by scanning electron microscopy (SEM), infrared absorptive spectrophotometry (IAS), and energy dispersive X-ray analysis (EDXA):
 - SEM shows a nonspecific “flake-like” appearance to the foreign material.
 - IAS and EDXA demonstrate the foreign material to be of fluorocarbon derivation.
 - The infrared spectrum of polytetrafluoroethylene (PTFE) exhibits a pair of intense bands in the 8- to 9-micron region in which the C-F bonds strongly absorb.
 - EDXA allows for unequivocal identification of Teflon in the tissue sections as seen by the major peak for fluorine at 0.68 keV.

Treatment and Prognosis

- Because Teflon is a permanent implant that is not absorbed, surgical resection remains the only way to remove the Teflon-induced granulomatous reaction.
- Once excised, patients experience improvement or disappearance of all related symptoms.
- Results of intracordal Teflon injection for vocal cord paralysis, in general, have been excellent with minimal complications.
- Teflon injection remains the preferred treatment in a select group of patients for alleviation of the symptoms associated with intractable unilateral vocal cord paralysis; although this is a safe and beneficial procedure, it may infrequently be associated with complications, the results of which may clinically mimic a neoplasm.

Tracheopathia Osteoplastica (TPO) (Figs. 15-23 and 15-24)

Definition: Segmental degenerative disorder of the tracheobronchial tree characterized by multiple, variable-sized submucosal osseous (and cartilaginous) nodules that may result in respiratory obstruction.

Synonym: Tracheobronchiopathia osteochondroplastica

- In contrast to aging larynx, in which there is often calcification of laryngeal cartilage, the tracheal cartilage does not calcify as readily and thereby retains its flexibility and functional integrity.

Clinical

- Uncommon disorder
- More common in men than in women; usually occurs in individuals over 50 years of age
- Patients may present with chronic cough, hemoptysis, dyspnea, stridor, and pulmonary infections; non-specific signs and symptoms may be present.
- There is an overall rigidity to the trachea.
- Endoscopically, irregular submucosal nodules can be seen protruding into the tracheal lumen:
 - Prominent sites of occurrence include the lower two thirds of the trachea and occasionally in the cervical trachea.
 - Posterior tracheal wall tends to be spared.
- Endoscopic appearance of multiple submucosal nodules often is diagnostic but an isolated or localized submucosal mass may be present, which can be clinically considered to represent a neoplasm resulting in tissue sampling:
 - Diagnosis confirmed by pathologic examination (see below)
- Radiology:
 - Sometimes the radiographic appearance demonstrates calcifications if there has been ossification within the nodules.
 - CT scan can reveal nodular thickening and irregularity of the anterior and lateral walls of the trachea; small calcified nodules along the inner aspect of the tracheal cartilage can be identified protruding into the tracheal lumen.
- Cause can possibly be linked to:
 - Chronic inflammation:
 - Many cases occur in patients with chronic inflammatory conditions, suggesting chronic inflammation as a possible cause.
 - Trauma
 - Suggestion that it is end stage of tracheal amyloidosis but there is no support for this contention

Pathology

Histology

- Submucosal irregular bony nodules with thin lamellar bony walls and fatty marrow:
 - Hematopoietic elements are not usually present.
 - Cartilage may be present in the nodules:
 - Calcifications may be present and usually are seen in limited (small) foci; rarely, extensive calcification is present.
- Continuity between the osseous or cartilaginous nodules with the tracheal cartilage may or may not be identified:
 - Absence of continuity has prompted the suggestion that the nodules are exostoses.
 - Continuity has prompted the suggestion that the nodules are metaplastic.

Fig. 15-23. Tracheopathia osteochondroplastica.

Contrast-enhanced axial images from a CT scan of the thorax demonstrate multiple osseous nodules and thickening of the anterior and lateral walls of the trachea (*arrows*), with sparing of the posterior membranous tracheal wall. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 32-31, p 2069.)

- The overlying mucosa is intact and may appear normal or metaplastic.
- Patients with significant narrowing may require laser removal and dilatation.

Differential Diagnosis

- Laryngeal myositis ossificans:
 - Zonal phenomenon of a highly cellular inner zone with a well-formed bone in the outer zone helps to distinguish this lesion from tracheopathia osteoplastica.
- Spindle cell squamous carcinoma

Treatment and Prognosis

- Localized disease may not require treatment.

Infectious Diseases of the Larynx and Trachea (Figs. 15-25 and 15-26)

- Larynx and trachea are subject to a wide variety of infectious disease, including bacterial, mycobacterial, viral, fungal, protozoal, and other infections.
- For a more complete discussion on specific microorganisms, see Section 1, Sinonasal Tract and Section 2, Oral Cavity.

Fig. 15-24. Histology of TPO.

Tracheopathia osteoplastica showing submucosal cartilaginous nodules with associated ossification. One of the nodules is in continuity with the underlying tracheal cartilage.

- This section provides a general overview of select infectious diseases.
- Acute laryngitis:
 - Designation used for an inflammatory disorder of usually short duration, lasting hours to days and affecting an otherwise healthy patient
 - Infectious causes are usually viral and bacterial.
 - Early in the disease course there is edema, a function of increased vascular dilatation, increased blood flow, and vascular stasis, resulting in increased vascular permeability and subsequent edema.
 - Larynx appears erythematous and there is associated pain
 - Acute viral laryngitis:
 - Usually result of viral inflammation of the upper respiratory tract
 - Rhinovirus and influenza virus are common (but not the only) pathogens.
 - Usually associated with other respiratory symptoms, including coryza, rhinorrhea, cough
 - Sore throat may herald the presence of pharyngitis and laryngitis.
 - Symptoms include voice changes, fever, pain on swallowing:
 - Onset of voice changes often delayed
 - Voice quality worse during resolution stages
 - Fever is low grade.
 - Vocal symptoms usually clear within 4 to 6 days, except in the immunocompromised patient, in whom acute laryngitis may persist and become chronic laryngitis:
 - Herpes simplex virus may be the cause of chronic laryngitis in this setting.

Fig. 15-25. Acute epiglottitis.

Postmortem specimen of acute epiglottitis in a pediatric patient showing the epiglottis, normally a well-defined structure, appearing beefy red and edematous with a rounded, thumb-like appearance.

- Most patients with viral laryngitis have a self-limiting course.
- Prognosis for return of voice is excellent.
- Acute bacterial (suppurative) epiglottitis:
 - Inflammation of epiglottitis caused by bacteria *Haemophilus influenzae*
 - Typically a pediatric-related disease referred to as pediatric epiglottitis or supraglottitis
 - Patients have high fever and epiglottitis.
 - May involve entire supraglottis but most often involves epiglottis and aryepiglottic folds
 - Epiglottis normally a well-defined structures appears cherry-red, edematous, enlarged, and less well-defined with a rounded, thumb-like density:
 - Edema may encroach on the vallecula and may rarely extend to the posterior pharyngeal wall.

Fig. 15-26. Mycobacterial laryngitis.

A, Endoscopic appearance of mycobacterial laryngitis in which the lesion has a granular, white appearance. **B**, Postmortem sections of the larynx in an immunocompromised patient with disseminated mycobacterial disease, including laryngeal involvement appearing as circumferential submucosal thickening. **C**, Histologically, there is diffuse infiltration of the laryngeal submucosa by vacuolated histiocytes rather than the classic caseating granulomas with multinucleated giant cells seen in immune-competent patients. **D**, Numerous mycobacteria are present within the vacuolated histiocytes (acid fast bacilli [AFB] staining; oil immersion).

- Hypopharynx, including the piriform sinus, may be involved.
- Subglottic extension and narrowing may rarely occur, particularly in children.
- May progress to airway compromise and require emergency airway management
- Supraglottitis in adults is usually different from that of children:
 - Most adults with supraglottitis do not develop airway obstruction typical of *Haemophilus influenzae* infection; rather the clinical presentation is mild with a benign course and with no definable pathogen.
 - A minority of adults may have a fulminant clinical course with acute respiratory compromise and blood cultures positive for *Haemophilus influenzae*.
- Infections associated with chronic laryngitis may include fungi, bacteria, viruses, and protozoa:
 - Fungal chronic laryngitis may include infection with *Candida*, *Blastomyces*, *Cryptococcus*, *Histoplasma*.
 - May be associated with pseudoepitheliomatous hyperplasia
 - Bacterial chronic laryngitis may include *Staphylococcus*, *Treponema pallidum*
 - *Helicobacter pylori* (HP) may be associated with chronic laryngitis as well as vocal fold minimal lesions (e.g., polyps, nodules, contact ulcers).
 - HP can be detected by immunohistochemical staining or reverse transcriptase polymerase chain reaction (RT-PCR).
 - Mycobacterial chronic laryngitis includes *M. tuberculosis* and atypical mycobacteria:
 - In immune intact patient the inflammatory reaction includes granulomatous inflammation with necrosis.
 - In immunocompromised patients unable to mount a granulomatous response there is a diffuse infiltration by vacuolated histiocytes, which contain the acid-fast microorganisms; mature lymphocytes and plasma cells may be present.
 - Viral chronic laryngitis may be caused by herpes simplex virus and cytomegalovirus.
 - Protozoa that may infect the larynx include *Leishmania* and *Trichinella* species.
- Other diseases that may be associated with chronic laryngitis include:
 - Sarcoidosis, a disease of uncertain cause, may also occur in the larynx and trachea and is associated with a noncaseating granulomatous inflammation (see Section 4, Pharynx).
 - Autoimmune diseases and connective tissue diseases, including:
 - Granulomatosis with polyangiitis (see above under [Subglottic Stenosis](#)):
 - Predilects to women
 - Tends to be localized to the subglottic region
 - Associated with elevated c-ANCA levels
 - Rheumatoid arthritis:
 - Laryngeal involvement is uncommon.
 - Most often involves the cricoarytenoid; less often the cricothyroid joint
 - Cricothyroid arthritis is usually bilateral.
 - Rheumatoid nodules develop in approximately 25% of patients with rheumatoid arthritis.
 - Nodules typically involve the true vocal cords; other sites of involvement may include the false vocal cords, epiglottis, or soft tissues around the cricoarytenoid joint.
 - Patients present with hoarseness, dysphonia, and dysphagia.
 - In acute phase of laryngeal involvement there may be inflammation, joint effusion, and a synovial proliferation.
 - Over time, joint destruction and ankylosis may develop.
 - Nodules are soft and often appear yellow.
 - Histologically, rheumatoid nodules are located within the submucosa and include the presence of granulomas characterized by fibrinoid necrosis of collagen surrounded by palisading histiocytes with associated fibrosis and inflammatory cells.
 - Surgical intervention (i.e., tracheotomy) may be required in the presence of ankylosis of the joints that may result in airway compromise.
 - Relapsing polychondritis (see Section 7, Ear and Temporal Bone)
 - Systemic lupus erythematosus
 - Sjögren syndrome:
 - Individuals with Sjögren syndrome predisposed to laryngopharyngeal reflux
 - High index of suspicion for laryngopharyngeal reflux should be maintained in all individuals with Sjögren syndrome.
 - Other systemic diseases that may involve the larynx include:
 - Crohn disease, IgG4-related disease, Rosai-Dorfman disease, others
 - Cutaneous-type dermatoses of the larynx may include:
 - Pemphigoid, pemphigus, epidermolysis bullosa, Darier disease (keratosis follicularis), Stevens-Johnson syndrome

Necrotizing Sialometaplasia

(Fig. 15-27)

- Represents benign, self-healing (reactive) inflammatory process of salivary gland tissue that clinically and histologically may be mistaken for a malignant neoplasm
- For a more complete discussion see Section 6, Salivary Glands.
- Most commonly involves the intraoral minor salivary glands particularly involving the palate; however, major salivary glands, as well as the minor salivary glands of virtually every site in the upper aerodigestive tract can be affected.
- Larynx and trachea may rarely be affected.
- Pathogenesis felt to be iatrogenically induced after an operative procedure, trauma, or radiotherapy:
 - Inciting event primarily but not exclusively thought to be due to ischemia
 - Mean duration of 18 days from the time of the insult to the development of lesion
- May occur de novo unassociated with a traumatic event or it may occur in association with a neoplasm (benign or malignant)
- Self-limiting usually healing by secondary intention:
 - Depending on the size of the lesion, the healing process in most cases occurs from 3 to 12 weeks.

Fig. 15-27. Laryngeal necrotizing sialometaplasia.

A, Necrotizing sialometaplasia of the supraglottic larynx characterized by the presence of submucosal rounded nests with preservation of the lobular architecture of seromucous glands; squamous metaplasia of the overlying epithelium is present. **B**, At higher magnification the sialometaplastic changes include replacement of the normal seromucous glands by benign squamous epithelium; the sialometaplastic nests are round with smooth contours. **C** and **D**, Foci of necrotic lobules showing retention of the rounded architecture of glands with complete necrosis of the epithelial components.

- Debridement and saline rinses may aid in the healing process.
- Recurrences do not usually occur.

Radiation-Associated Changes

(Fig. 15-28)

- Radiation-associated injury to the upper aerodigestive tract (UADT), including the larynx (and pharynx), is fairly common owing to the use of radiation treatment as primary therapy for mucosal-based carcinomas, especially squamous cell carcinoma, of these sites.

Fig. 15-28. Radiation-associated changes.

Chronic radiation-associated alterations of the laryngeal mucosa may include (A) thinning and reactive atypia of the surface squamous epithelium with submucosal stromal edema, telangiectatic capillaries showing the presence of prominent (plump) endothelial cells, and scattered individual atypical appearing fibroblasts; (B) at higher magnification, the atypical fibroblasts (arrows) have “smudged”-appearing nuclei and an absence of cohesive cellular groupings; these findings assist in distinguishing radiation change from (residual/recurrent) squamous cell carcinoma.

- Radiation injury to mucosal sites includes alterations in the surface epithelium, minor salivary glands, fibroblasts, skeletal muscle, and endothelial cells.
- Radiation-induced changes may be acute or chronic:
 - Acute changes occur from days to weeks (usually 6 weeks) after treatment.
 - Chronic changes are seen from 6 to 7 weeks after therapy to years later.
- Biopsies are taken after radiation therapy to primarily exclude the possibility of (recurrent) carcinoma:
 - Not uncommonly, may be requested as an intra-operative consultation (i.e., frozen section)
- Postradiation histomorphologic alterations include:
 - Acute postirradiation phase (days to weeks) biopsies are seldom obtained:
 - Degeneration and focal necrosis of basal zone epithelium
 - Submucosal edema with dilation of capillaries and associated swelling of endothelial cells
 - Glandular and acini distention containing mucus
 - Superficial erosions with pseudomembranes (3 to 4 weeks postradiation)
 - Approximately 1 month after initiation of therapy squamous epithelium usually shows complete restoration although thinner than normal.
 - Chronic postirradiation histologic changes are variable and may include:
 - Thinner-than-normal surface epithelium
 - Surface ulceration
 - Squamous epithelial atypia; may be so pronounced as to suggest carcinoma but in the chronic postirradiation phase most such examples are usually not indicative of carcinoma
 - Atrophy of minor salivary gland acini
 - Squamous metaplasia (sialometaplasia) of minor salivary glands:
 - May include marked cytologic atypia, suggesting a possible diagnosis of squamous cell carcinoma
 - In contrast to invasive squamous cell carcinoma that typically results in effacement of lobular architecture of minor salivary glands, retention of the lobulated outline of the minor salivary glands supports a diagnosis of sialometaplasia.
 - Submucosal fibrosis
 - Vascular alterations characterized by telangiectatic capillaries often with prominent (plump) endothelial cells, myointimal proliferation, foamy histiocytes within the intima, and thrombosis
 - Atypical (bizarre) fibroblasts:
 - Generally appear as individual cells with “smudged”-appearing nuclei in association

with other histologic alterations of radiation changes

- Absence of cohesive cellular grouping as may be seen in invasive carcinoma
- Immunohistochemical staining for epithelial markers (e.g., cytokeratins, p63, others) may be required to differentiate squamous cell carcinoma (positive staining) from radiation-induced atypical fibroblasts (negative staining)
- Bizarre striated muscle degeneration
- For a more complete discussion of radiation-related injury see Section 2, Oral Cavity.

LARYNGEAL BENIGN (NON-NEOPLASTIC) EPITHELIAL CHANGES (Figs. 15-29 through 15-32)

Benign epithelial changes include clinical and histopathologic terms, including:

Clinical terms:

- Leukoplakia:
 - Any white lesion on a mucous membrane
 - Associated with increased risk of underlying significant dysplasia but not necessarily indicative of underlying significant dysplasia (i.e., moderate or severe) or carcinoma
- Erythroplakia:
 - Any red lesion on a mucous membrane
 - Often indicative of an underlying significant dysplasia (i.e., moderate or severe) or carcinoma
- Speckled erythroplakia:
 - Mixed red and white lesion on a mucous membrane
 - Often indicative of an underlying significant dysplasia (i.e., moderate or severe) or carcinoma

Histopathologic terms:

- Hyperplasia:
 - Thickening of an epithelial surface as a result of an absolute increase in the number of cells
- Pseudoepitheliomatous hyperplasia (PEH):
 - Exuberant reactive or reparative overgrowth of squamous epithelium (hyperplasia) displaying no cytologic evidence of malignancy:
 - May be mistaken for an invasive squamous cell carcinoma
 - May be seen in association with certain tumors (e.g., granular cell tumor) or in setting of an infectious disease (e.g., fungus, others)
- Keratosis:
 - Abnormal presence and/or excessive keratin on an epithelial surface
 - Use of the term *hyperkeratosis* is redundant and unnecessary as it applies to the larynx because

under normal conditions the resting laryngeal epithelium is nonkeratinizing.

- Parakeratosis:
 - Presence of nuclei in keratin layer
- Orthokeratosis:
 - Absence of nuclei in keratin layer
- Dyskeratosis:
 - Abnormal keratinization of epithelial cells
 - Applies to cells located away from the superficial aspects of the surface epithelium
- Ulceration:
 - Erosion and/or loss of the surface epithelium
- Metaplasia:
 - Change from one histologic tissue type to another and generally occurs as a result of tissue insult or injury
- Koilocytosis
 - Descriptive term for cytoplasmic vacuolization of squamous cells
 - Morphologic change suggestive of viral (human papillomavirus) infection
- Atypia:
 - Vague term that has been liberally used spanning alterations, including those that are reactive as well as those that are dysplastic
 - In the presence of bona fide dysplastic changes, preference should be to use the designation dysplasia rather than atypia to exclude reactive changes typically not requiring further therapy and to indicate potentially irreversible cytomorphic findings typically requiring additional therapy
- Above morphologic changes may be identified in an array of pathologic lesions and are not necessarily specific for any single disease (Table 15-1).

Histomorphologic changes in a malignant (irreversible) direction include:

- Dysplasia:
 - Abnormal maturation and cellular aberrations
 - Graded as mild, moderate, or severe
- Carcinoma in situ (CIS):
 - Full-thickness intraepithelial dysplastic change in the presence of an intact basement membrane
 - Any violation of the basement by dysplastic cells generally equates to invasive carcinoma.
 - Involvement of seromucous glands by dysplastic cells represents extension of the intraepithelial dysplasia and not invasive carcinoma.
- Superficially invasive or microinvasive (squamous cell) carcinoma
 - Squamous carcinoma in which there is violation of the basement membrane with invasion into the underlying stroma:
 - No clear definition of what constitutes invasion with some authorities advocating invasion to no greater than 0.5 mm as measured from

Fig. 15-29. Laryngeal leukoplakia.

A, Focal flat, white lesion along the anterior true vocal cord. **B**, In contrast to the previous example this lesion is raised and more diffuse in its extent (pachyderma larynges). **C**, Another example of laryngeal leukoplakia with a papillary or verrucoid appearance.

Fig. 15-30. Laryngeal keratosis without dysplasia.

A, Orthokeratotic epithelium with hypergranulosis. **B**, Papillary or verrucoid keratosis with parakeratosis. **C**, Flat keratosis with parakeratosis. All of these examples show irregular epithelial hyperplasia without dysplasia. A variable chronic inflammatory cell reaction is seen in the submucosa.

Fig. 15-31. Pseudoepitheliomatous hyperplasia due to fungal infection.

This laryngeal leukoplakic lesion was clinical suspicious for a carcinoma. **A**, At low magnification there is a keratotic epithelial proliferation with downward extension of the rete pegs, raising concern for a possible diagnosis of carcinoma. **B**, At higher magnification there is dyskeratosis, as well as neutrophilic infiltrate along the surface epithelium and within the deeper epithelial layers. **C**, Periodic acid Schiff staining shows the presence of fungal hyphae within the depth of the epithelium indicative of fungal (*Candida*) infestation with secondary pseudoepitheliomatous hyperplasia. In contrast, fungal colonization may or may not have associated neutrophilic infiltrate, but the fungal forms (spores and hyphae) are limited to the surface and/or superficial squamous epithelium rather than within the depth of the surface epithelium.

Fig. 15-32. Viral cytopathic changes.

Human papillomavirus (HPV)-associated changes in a biopsy performed for a leukoplakic laryngeal lesion and a histologic diagnosis of keratosis without dysplasia (not shown). **A**, Tissue fragment showing papillary keratosis with cytopathic viral changes (i.e., koilocytes). **B**, Immunostaining confirming the presence of HPV 6/11.

TABLE 15-1 Pathologic Abnormalities of the UADT Mucosal Surface Epithelium

Morphologic Change	Pathologic Lesion(s)
Hyperplasia/acanthosis	Benign reactive processes, infectious diseases, papillomas, intraepithelial dysplasias, carcinoma
Keratosis/parakeratosis/orthokeratosis	Benign reactive processes, infectious diseases, papillomas, intraepithelial dysplasias, carcinoma
Ulceration and/or necrosis	Benign reactive processes, infectious diseases, polyps, papillomas, other benign neoplasms, intraepithelial dysplasias, carcinoma
Pseudoepitheliomatous hyperplasia	Benign reactive processes, infectious diseases, polyps, papillomas, granular cell tumor, intraepithelial dysplasias, carcinoma
Papillary/verruroid growth	Benign reactive processes, infectious diseases, intraepithelial dysplasias, carcinoma
Koilocytosis	Benign reactive processes, verrucae, papillomas, carcinoma
Dyskeratosis	Benign reactive processes, infections/inflammatory conditions, papillomas, intraepithelial dysplasias, carcinoma
Metaplasia	Benign reactive processes, radiation-associated, intraepithelial dysplasias, carcinoma

UADT, Upper aerodigestive tract.

the epithelial basement membrane and other authorities advocating invasion limited to 1 to 2 mm from the epithelial basement membrane

- Identification of superficial or microinvasive carcinoma is significant given the presence of vascular spaces high in the lamina propria so that access to vessels may occur in the face of limited invasion, potentially resulting in metastatic disease.

Hyperplastic Epithelial Changes

Definition: Potentially reversible reactive or reparative benign process reflecting the epithelial response to a stimulus or to injury.

Synonyms: Keratosis without dysplasia; hyperplasia without dysplasia

Clinical

- More common in men than in women; generally limited to the adult population with a mean age at diagnosis in the sixth decade of life
- May occur anywhere in the larynx but identified mainly along the true vocal cord:
 - Typically unilateral proliferation but may be bilateral in up to 30% of cases
- Most frequent symptom is hoarseness.
- Causes may include:
 - Tobacco smoking
 - Excess alcohol use
 - Chronic infections, including (but not limited to) fungal infection
 - Less commonly secondary to voice abuse, environmental/industrial exposure, laryngopharyngeal reflux, and vitamin A deficiency

Pathology

Gross

- Array of appearances including a flat (most common), papillary, or verrucoid lesion with a white (leukoplakic) or red (erythroplakic) appearance
- May be localized to a small area of the vocal cord or may be diffuse, involving virtually the entire larynx (pachyderma laryngis)

Histology

- Variably include:
 - Thickening of the surface epithelium by an absolute increase in the number of cells (simple epithelial hyperplasia)
 - Presence of a superficial keratin layer (keratosis) or nuclei in the superficial keratin layer (parakeratosis)
 - Overall appearance or configuration may include papillary, exophytic, or verrucoid.

- Presence of keratohyaline granules in granulosal cell layer
- Absence of significant cytologic atypia
- Dyskeratosis may be present.
- Koilocytosis may or may not be present.
- Nonspecific chronic inflammatory cell reaction may be present in the submucosa with extension into the surface epithelium.
- An acute inflammatory cell reaction (i.e., neutrophils) may be seen in the superficial layers of the surface epithelium and/or within the depths of the surface epithelium:
 - Presence of neutrophils should prompt consideration for a possible infectious cause, specifically the presence of fungal forms (spores and/or hyphae).
 - Presence of neutrophils and/or microorganisms does not exclude a possible diagnosis of a coexisting significant dysplasia and/or carcinoma.
- Special stains for fungi including periodic acid Schiff (PAS) and/or Gomori methenamine silver (GMS) may be required to identify fungal forms (spores and/or hyphae):
 - Fungal infestation may result in epithelial changes that clinical and morphologically raise concern for a diagnosis of squamous cell carcinoma.
 - Fungal forms should be identified within the depth of the epithelium to diagnose fungal infestation.
 - Presence of fungal forms on the surface or within the superficial keratin layer represents colonization and not infestation.
- Viral-related changes (i.e., koilocytosis) may be identified:
 - Presence of koilocytosis can be seen in a variety of lesions, including in association with hyperplastic (reactive) epithelial changes.
 - Koilocytosis is not necessarily a premalignant finding or an indicator of potential progression to a malignancy.
 - Presence of koilocytosis correlates to low-risk human papillomavirus (HPV), including types 6/11.
 - To date, high-risk HPV not associated with intraepithelial dysplasia, papillomas, and/or carcinomas of the laryngeal (and tracheal) mucosa:
 - No diagnostic or therapeutic utility to using immunohistochemical staining (i.e., p16) and/or molecular diagnostic testing (in situ hybridization, polymerase chain reaction) to evaluate for the presence of HR HPV
- Immunohistochemistry, cytogenetic and molecular genetics:
 - p53 overexpression may be present:
 - Not a discriminator between keratosis without dysplasia from premalignant lesions

- Matrix metalloproteinases (MMPs) is a family of proteolytic zinc-containing enzymes, responsible for breakdown of the extracellular matrix components in pathologic and physiologic conditions.
 - MMPs involved in basement membrane disruption, stroma and blood vessel penetration, metastasis, and more evidence of their participation in tumor growth and angiogenic events
 - MMP9 belongs to the gelatinases, a subgroup of MMPs having the capacity to degrade the triple helix–type IV collagen of basal lamina of the basement membrane.
 - MMP9 expression significantly higher in dysplastic laryngeal lesions as compared with benign lesions, including keratosis without dysplasia
- Close clinical follow-up of patients advised
- Cessation of potentially contributing causes (e.g., smoking, excessive alcohol use, other) strongly advocated
- If associated etiologic factors are identified then attempts to control the inciting cause should be attempted:
 - For fungal infestation antimicrobial therapy is indicated.
- Risk of development of an invasive carcinoma in the face of a hyperplastic process without significant dysplasia is minimal:
 - Incidence of invasive carcinoma developing in lesions diagnosed as keratosis without dysplasia approximately 5%
 - Approximately 7% of cases showing keratosis without dysplasia will progress to keratosis with dysplasia:
 - Risk of developing an invasive carcinoma in lesions diagnosed as keratosis with dysplasia approximately 18%
 - Risk for progression to invasive carcinoma in lesions diagnosed as keratosis with dysplasia varies depending on the degree of dysplasia:
 - For mild dysplasia: approximately 6%
 - For moderate dysplasia: approximately 23%
 - For severe dysplasia: approximately 28%
 - For those lesions that progress to invasive carcinoma the average latency period from the diagnosis of keratosis with atypia to invasive carcinoma is 3.8 years.

Differential Diagnosis

- Contact ulcer
- Verruca vulgaris
- Keratosis with dysplasia:
 - Demographics and clinical features similar to those of keratosis without dysplasia
 - In contrast to keratosis without dysplasia, these lesions show variable dysplasia ranging from mild to moderate to severe.
 - See Chapter 16 on premalignant lesions for a more complete discussion.
- Well-differentiated (“conventional”) squamous cell carcinoma
- Papillary (exophytic) squamous cell carcinoma
- Verrucous carcinoma

Treatment

- Excisional biopsy by vocal cord stripping or by forceps is the preferred treatment.
 - Potentially reversible process
 - Lesions that qualify as keratosis without dysplasia require no additional therapy.

Neoplasms of the Larynx and Trachea

CLASSIFICATION OF NEOPLASTIC LESIONS OF THE LARYNX AND TRACHEA (Box 16-1)

BOX 16-1 Classification of Laryngeal and Tracheal Neoplasms

Benign

Epithelial

- Papilloma/papillomatosis (recurrent respiratory papillomatosis)
- Minor salivary gland tumors

Mesenchymal/Neuroectodermal

- Granular cell tumor
- Nodular fasciitis
- Inflammatory myofibroblastic tumor
- Chondroma
- Rhabdomyoma
- Hemangioma
- Neurilemoma/neurofibroma
- Leiomyoma
- Fibrous histiocytoma
- Lipoma
- Paraganglioma
- Others

Premalignant Epithelial Lesions

- Dysplasias, keratinizing and nonkeratinizing

Malignant

Epithelial

- Squamous cell carcinoma:
 - Carcinoma in situ
 - Microinvasive carcinoma
 - Invasive squamous cell carcinoma
- Papillary (exophytic) squamous cell carcinoma

- Verrucous carcinoma
- Spindle cell squamous carcinoma
- Basaloid squamous carcinoma
- Adenosquamous carcinoma
- Lymphoepithelial-like carcinoma
- Giant cell carcinoma
- Minor salivary gland tumors:
 - Adenoid cystic carcinoma
 - Mucoepidermoid carcinoma
 - Others

Neuroectodermal

- Neuroendocrine carcinomas:
 - Carcinoid tumor
 - Atypical carcinoid tumor
 - Small cell undifferentiated neuroendocrine carcinoma
 - Large cell neuroendocrine carcinoma
- Mucosal malignant melanoma

Mesenchymal

- Chondrosarcoma
- Synovial sarcoma
- Liposarcoma
- Rhabdomyosarcoma
- Angiosarcoma/Kaposi sarcoma
- Leiomyosarcoma
- Hematolymphoid
- Others

Secondary Tumors

GENERAL CONSIDERATIONS

- Similar to tumors of other upper aerodigestive tract sites, most common tumors of the larynx are of epithelial origin:
 - Most common benign neoplasm is a (squamous) papilloma
 - Most common malignant neoplasm is squamous cell carcinoma or variant thereof, accounting for greater than 95% of all malignant neoplasms of the larynx

- Primary tumors of the trachea are rare and ratio of benign to malignant tumors varies per age of the patient:
 - In pediatric ages benign tumors > malignant tumors:
 - 60% to 90% of tumors are benign:
 - Most common are squamous papillomas, hemangioma, granular cell tumor
 - 10% to 40% are malignant:
 - Most common is mucoepidermoid carcinoma

- In adult ages malignant tumors > benign tumors:
 - 90% of tumors are malignant:
 - Most common (95% of total) are squamous cell carcinoma and its variants
- Most common benign neoplasm is a (squamous) papilloma
- For more detailed discussion on a variety of factors related to laryngeal and tracheal carcinoma, see later in this chapter under site-specific squamous cell carcinoma.

BENIGN NEOPLASMS OF THE LARYNX AND HYPOPHARYNX

LARYNGEAL PAPILOMA/ PAPILLOMATOSIS; RECURRENT RESPIRATORY PAPILLOMATOSIS

(Figs. 16-1 through 16-6)

Definition: Benign, exophytic epithelial neoplasm composed of branching fronds of squamous epithelium with fibrovascular cores that may be single or multiple and may be associated etiologically with low-risk human papillomavirus types 6 and 11.

Synonyms: Squamous papilloma; laryngeal papillomatosis; recurrent respiratory papillomatosis, juvenile papillomatosis, adult papillomatosis; nonkeratinized papilloma; keratinized papilloma; papillary keratosis

- At present, the preferred terminology for viral-associated papillomas that are nonkeratinizing, tend to persist or recur, and show a degree of resistance to treatment is recurrent respiratory papillomatosis.
- Most common benign neoplasm occurring in this anatomic region
- Due to distinct clinical and histopathologic findings, papillomas can be separated by:
 - Age: juvenile versus adult forms
 - Number of lesions: solitary versus multiple
 - Histology: nonkeratinizing and keratinizing

Recurrent Respiratory Papillomatosis (Nonkeratinizing Papilloma) (Table 16-1)

Clinical

- Divided into:
 - Lesions that occur in early years referred to as juvenile-onset recurrent respiratory papillomatosis (JO-RRP)
 - Lesions that occur in older ages referred to as adult-onset recurrent respiratory papillomatosis (AO-RRP)
 - Age separating juvenile versus adult onset not established and different studies cite different ages

Fig. 16-1. Recurrent respiratory (laryngeal) papillomatosis.

A, The lesion is characterized by an exophytic, warty, tan-white appearance. **B,** Resected portion of larynx showing characteristic papillary appearance with intraluminal growth.

Fig. 16-2. Recurrent respiratory (laryngeal) papillomatosis.

Left, Histologic appearance is characterized by papillary fronds of multilayered squamous epithelium containing fibrovascular cores. *Right*, Benign epithelium of the papilloma is seen; the majority of these lesions lacks keratinization.

- Although not universally accepted, 20 years of age can serve as a potential dividing line between JO-RRP and AO-RRP.

JO-RRP

- No gender predilection; most patients become symptomatic at an early age, including 2 to 5 years of age.
- Clinical presentation includes changes in phonation (e.g., abnormal crying, hoarseness), dyspnea, cough, dysphagia, stridor.
- Majority are multiple (rather than a single lesion) with extensive growth and rapid recurrence:
 - May remit spontaneously or persist into older ages

AO-RRP

- More common in men than in women; affects all age groups but most common from ages 20 to 40
- Clinical presentation includes changes in phonation (e.g., hoarseness).
- Majority are single (rather than multiple) and tend to recur less often.

JO-RRP and AO-RRP

- Primarily a disease of the larynx:
 - May occur anywhere in the larynx but most often involve the true and false vocal cords, ventricles, and subglottis
 - Spread to nearby (extralaryngeal) areas may occur and include oral cavity and tracheobronchial tree:

Fig. 16-3. Dysplasia in laryngeal papilloma.

The dysplastic changes occurred over time and only after multiple recurrences. **A**, Dysplastic features include the presence of immature-appearing cells with nuclear hyperchromasia, pleomorphism, increased nuclear-to-cytoplasmic ratio, and loss of cell polarity. **B**, HPV cytopathic changes (i.e., koilocytes) are seen; immunostaining confirmed the presence of HPV 6/11 (not shown).

- Extralaryngeal spread occurs more commonly in children than in adults.
- Extension into and down tracheobronchial tree occurs in approximately 5% of patients.
- RRP tends to localize to those junctional areas where ciliated respiratory epithelium meets squamous epithelium referred to as squamous epithelial-ciliary respiratory epithelial junction (SCJ) and include:
 - Histologically normal junctional mucosa (e.g., supraglottic-glottic junction or glottic-subglottic junction)
 - Areas in which there is metaplastic alteration secondary to an injury with squamous epithelium replacing ciliated respiratory epithelium creating a new squamous epithelial-ciliated respiratory epithelial junction

Fig. 16-4. Spread of papillomatosis.

Progression of recurrent respiratory (laryngeal) papillomatosis may include **(A)** extension of the papillomas from the glottic region into the subglottis and down the tracheobronchial tree; **(B)** extension into the lungs. The histology of all of these papillomata was that of typical (benign) papilloma without dysplasia or evidence of carcinoma.

Fig. 16-5. Malignant transformation.

Rare example of malignant transformation of recurrent respiratory (laryngeal) papillomatosis that occurred in a teenage girl. **A**, Laryngectomy specimen showing the neoplasm invading into and through cartilage. **B**, The histology of the carcinoma was that of a well-differentiated squamous cell carcinoma. **C**, The carcinoma metastasized to paratracheal and cervical neck lymph nodes.

- Cause:
 - Virally induced caused by low-risk human papillomavirus (HPV)
 - HPV types 6 and 11 most frequent types identified:

Fig. 16-6. Laryngeal verruca vulgaris.

Laryngeal verruca vulgaris characterized by verrucoid growth, marked keratosis, prominent granular cell layer, and coarse, irregular keratohyaline granules.

- Rarely, HPV 16, 18, 31, 33, and 35 identified
- Mode of transmission:
 - In JO-RRP a significant percentage of patients (up to 70%) born to women with uterine cervical condylomas with transmission related to maternal-genital infection:
 - JO-RRP has been correlated to the triad of (1) first-born child, (2) vaginal delivery, and (3) teenage mother.
 - Vaginal condyloma in pregnancy is strongly predictive of JO-RRP.
 - Cesarean section rather than vaginal delivery has been advocated in this clinical setting but cesarean section has not been entirely protective from infection and the development of RRP.
 - In AO-RRP the mode of transmission remains uncertain; considerations include:
 - Possibility of maternal transmission during delivery with the virus remaining dormant until adulthood when there is activation of virus
 - Orogenital contact with an infected individual

TABLE 16-1 Laryngeal Papillomas: Clinical-Pathologic Features

	JO-RRP	AO-RRP	Keratinizing Papilloma
Age	Less than 20 years*	20 years and older*	Occurs in adults
Gender	No gender predilection	Much more common in men than in women	No gender predilection
Symptoms	Changes in phonation, stridor, dysphagia, cough	Hoarseness	Hoarseness
Sites	SCJ includes supraglottic-glottic junction or glottic-subglottic junction	SCJ includes supraglottic-glottic junction or glottic-subglottic junction	True vocal cord is the most common location
Lesions	Majority are multiple (80% to 98%)	Majority are single (65% to 75%)	Usually single
Pathology	Papillary fronds of multilayered benign squamous epithelium containing fibrovascular cores with little or no keratin	Papillary fronds of multilayered benign squamous epithelium containing fibrovascular cores with little or no keratin	Papillary fronds of multilayered benign squamous epithelium containing fibrovascular cores with associated keratinization (parakeratosis or orthokeratosis); kerato-hyaline granules may be present
HPV	Present usually 6 and 11 rarely high-risk types	Present usually 6 and 11 rarely high-risk types	Absent
Treatment	Surgical excision	Surgical excision	Surgical resection
Prognosis	Variable often with recurrent disease	Variable	Usually cured after excision
Malignant transformation	2% in nonirradiated cases 14% irradiated cases	2% in nonirradiated cases 14% irradiated cases	Rare

AO-RRP, Adult-onset recurrent respiratory papillomatosis; JO-RRP, juvenile-onset recurrent respiratory papillomatosis; SCJ, squamous epithelial-ciliary respiratory epithelial junction.

*Not universally accepted as the dividing age limit.

Pathology

Gross

- Single or multiple exophytic, warty, friable, tan-white to red growth(s)
- Characteristic feature is ease of bleeding after minor trauma.

Histology

- Papillary fronds of multilayered benign squamous epithelium containing fibrovascular cores
- Little or no surface keratin production although an occasional case may have keratinization (parakeratosis or orthokeratosis)
- Stroma well vascularized; variable amount of inflammatory cells are present
- A certain degree of cellular atypia may be seen especially in those lesions that recur over short periods of time:
 - Generally the degree of dysplasia is limited and the risk of progression to a more significant dysplastic lesion or carcinoma is low.
 - Atypical features include basal zone hyperplasia with nuclear pleomorphism, increased nuclear-to-cytoplasmic ratio, loss of cell polarity, prominent nucleoli, and increased mitotic activity; dyskeratosis may also be identified.
 - Presence of severe atypia may be indicative of the development of squamous carcinoma arising in papillomatosis or may in fact represent an exophytic squamous cell carcinoma.
 - In presence of dysplasia majority are positive for low-risk HPV subtypes so that high-risk HPV subtypes do not predispose patients with laryngeal papilloma to dysplasia
- Viral-induced changes (i.e., koilocytosis) may be seen.
- Immunohistochemistry:
 - Immunostains for HPV may be positive:
 - When virus is present majority are HPV 6/11.
 - p16 typically negative:
 - Patchy p16 reactivity may be present but such reactivity does not represent positive staining.
 - Positive staining requires diffuse and strong nuclear and cytoplasmic staining in at least 75% of the lesions.
 - p53 negative
- Cytogenetics and molecular genetics:
 - Identification of viral antigens or genomes by in situ hybridization and polymerase chain reaction
 - In situ hybridization for angiogenic growth factor VEGF-A has shown strong expression in the epithelium of squamous papillomas in RRP, as well as strong expression of VEGFR-1 and VEGFR-2

mRNAs by underlying vascular endothelial cells, suggesting a role for VEGF-A in the pathogenesis of RRP.

Differential Diagnosis

- Verruca vulgaris:
 - Typically occurs in cutaneous sites
 - Infrequently occurs in mucosal sites, including lips
 - Etiologically linked to HPV:
 - HPV 2 and 4 typically associated with VV of the skin, lips, and oral cavity
 - HPV 6 and 11 identified in laryngeal VV
 - Rare lesion of the larynx:
 - Much more common in men than in women; disease of adults
 - Most common on the true vocal cord
 - Hoarseness is the most common symptom.
 - Exophytic, demarcated warty-appearing white lesion usually measuring less than 1 cm
 - Histologically similar to verruca vulgaris of the skin and includes:
 - Verrucoid appearance
 - Keratosis
 - Prominent granular cell layer
 - Coarse and irregular keratohyaline granules
 - Thin, pointy rete pegs
 - Presence of koilocytes
 - Simple excision is curative.
 - Recurrence may rarely occur.
- Verrucous carcinoma
- Papillary or exophytic squamous cell carcinoma

Treatment and Prognosis

- Because of the unpredictable nature of disease, which may be characterized by periods of active growth and remission, best mode of treatment and the efficacy of treatment remain uncertain:
 - Presently recommended treatment for RRP is surgery, including microlaryngeal excision with CO₂ laser surgery
 - Adjunctive drugs used in treatment with varying success include interferon, various virostatics (e.g., acyclovir, valacyclovir, and cidofovir), and indole-3-carbinol
 - Vaccination with a quadrivalent vaccine against HPV types involved most commonly in RRP may provide the best hope to prevent severe forms of this disease.
- In general, treatment should be as conservative as possible with the primary aims of therapy to include:
 - Airway maintenance
 - Voice preservation
 - Reduction of tumor burden with the goal of disease eradication
 - Avoidance of tracheotomy:

- Tracheotomy may be required to maintain a functional airway in as high as 65% of patients.
- On average tracheotomy is required in approximately one third of patients.
- If tracheotomy is required, then the maintenance of airway patency and use of the shortest tracheotomy tube are advised.
- Complications of surgery may include:
 - Laryngoceles
 - Scarring
 - Stenosis
 - Arytenoid fixation
- Radiotherapy is contraindicated because of its associated complications, including:
 - Laryngeal destruction, scarring, and laryngeal stenosis and the risk of inducing malignant transformation
 - 16-fold increased risk of developing carcinoma in patients who have been irradiated
- Recurrence of tumor is common, requiring long-term and repeated management:
 - Recurrence correlates with persistence of HPV.
 - HPV can be identified in nonpapillomatosis mucosa adjacent to the papilloma in as many as 75% of patients:
 - Identification of HPV in nondiseased mucosa by in situ hybridization and polymerase chain reaction
- Variability of disease course is reflected in the unpredictable nature of recurrent tumor:
 - Some patients experience one or two recurrences over a few-year period followed by spontaneous remission.
 - Other patients have frequent recurrences over very short periods of time (weeks), necessitating multiple operative procedures.
 - Other patients may have repeated recurrences over short periods of time and then remain disease free for decades only to have multiple recurrent diseases later in life, necessitating multiple operative procedures.
 - Appears that patients with RRP are at risk throughout their lives for the possibility of local recurrence
 - In approximately 80% of patients disease persists for 5 years or longer.
 - Effect of puberty and pregnancy on the course of disease remains controversial:
 - In some patients the disease resolves or becomes less aggressive in puberty or pregnancy.
 - In some patients the disease progresses/becomes more aggressive in puberty or during pregnancy.
- Overall mortality rate varies from 2% to 14%:
 - Extension into the tracheobronchial tree occurs in 2% to 15% and involvement of lower respiratory tract parenchyma is associated with increased mortality rates.
- Death may be caused by asphyxiation, superimposed infection, and malignant transformation.
- Carcinoma developing in RRP may occur in nonirradiated and in irradiated patients:
 - Overall incidence of developing carcinoma in nonirradiated patients is 2%.
 - Overall incidence of developing carcinoma in irradiated patients is 14%.
 - Carcinoma developing in the setting of RRP is squamous cell carcinoma.
 - Transformation of RRP to squamous cell carcinoma may:
 - Be spontaneous, not characterized by histologic progression, through dysplasia over time
 - Develop through a continuum of dysplasia over time
 - Transformation to squamous cell carcinoma may result in loss of HPV expression.
 - Carcinoma developing in RRP may develop in larynx or in the lung.
 - Laryngeal carcinomas developing spontaneously (i.e., in nonirradiated patients) tend to:
 - Occur in JO-RRP
 - Develop decades after disease onset
 - Have lower mortality rates
 - Laryngeal carcinomas developing in irradiated patients tend to:
 - Occur in JO-RRP
 - Develop in shorter interval periods (decade or less) after disease onset
 - Have higher mortality rates
 - Lung carcinomas developing in nonirradiated and nonsmoking patients tend to:
 - Have early onset of RRP ranging in age from 1 to 6 years with an average age of onset of 2½ years
 - Have disease extension down the tracheobronchial tree into the lungs
 - Develop carcinoma approximately 25 years after laryngeal disease
 - Often have metastatic disease (regional lymph nodes and distant)
 - Have high mortality rates usually over short periods of time following the diagnosis of carcinoma
 - Factors in RRP reported to be associated with increased risk of aggressive behavior with spread to lower airway passages, malignant transformation, and death include:
 - Patients with HPV type 11:
 - Malignant transformation reported solely for HPV 11-associated RRP in 2% to 4% of all RRP cases

- Malignant transformation not reported to be associated with HPV 6; however, a patient with HPV 6 expressing E6 and E7 oncogenes shown to follow similar aggressive clinical course as patients with HPV 11
 - These patients developed disease at a younger age and expressed higher levels of E6 and E7 oncogenes compared with the patients with more indolent course.
- Alterations of aldo-keto reductase 1C3 gene (AKR1C3) on chromosome 10p15.1 may be implicated in carcinogenesis.
- Severity score of greater than 4:
 - Includes functional assessment of clinical parameters and an anatomic assessment of disease distribution
 - Anatomic score can then be used in combination with the functional score to measure an individual patient's clinical course and response to the therapy over time.
- A high number of surgical procedures prior to interferon-alpha therapy

Keratinizing Papilloma (Papillary Keratosis) (see Table 16-1, Fig. 16-7)

Clinical

- No gender predilection; disease of adults but may occur over a wide age range, including patients younger than 50 years of age
- Tend to occur on the true vocal cord
- Patients usually present with hoarseness.
- Cause:
 - Not etiologically linked to human papillomavirus (unlike nonkeratinizing papillomas)
 - Reported to occur in patients with smoking history

Pathology

Gross

- Exophytic or papillary lesion with a white appearance, usually does not exceed 2 cm in greatest dimension.

Histology

- Papillary fronds of multilayered benign squamous epithelium containing fibrovascular cores with associated keratinization
- Keratinization may be in the form of parakeratosis or orthokeratosis.
- Keratohyaline granules can be identified.
- In most examples there is an absence of cytologic dysplasia (i.e., keratinizing papilloma or papillary keratosis without dysplasia):

Fig. 16-7. Keratinizing papilloma.

A, B, Laryngeal keratinizing papilloma composed of papillary fronds of multilayered benign squamous epithelium containing fibrovascular cores and associated surface keratosis and parakeratosis; a sparse neutrophilic cell infiltrate is present.

- Dysplasia can be seen ranging from mild to moderate to severe and should be reported as such (i.e., keratinizing papilloma or papillary keratosis with mild, moderate, or severe dysplasia).
- In general, a high threshold should be maintained to diagnose dysplasia because laryngeal papillomas in general and squamous papillomas of the entire upper aerodigestive tract tend to be resistant to developing high-grade intraepithelial dysplasia (i.e., moderate to severe dysplasia).
- A variable mixed inflammatory cell infiltrate may be present in the stroma.

Differential Diagnosis

- Verrucous carcinoma
- Papillary or exophytic squamous cell carcinoma

Treatment and Prognosis

- Surgical resection is usually curative.
- Usually do not recur but occasionally may recur
- Rarely undergo malignant transformation to a carcinoma

BENIGN SALIVARY GLAND TUMORS

- Laryngeal benign salivary gland tumors are extremely rare:
 - Laryngeal malignant salivary gland tumors are more common than benign ones.
- Most common tumor type is pleomorphic adenoma.
- Most often occur in supraglottic larynx
- Histology is identical to pleomorphic adenomas of more common locations (i.e., salivary glands).
- Another category of salivary gland lesions include oncocytic papillary lesions:
 - Controversial category
 - Various designated oncocytic cyst, oncocytic papillary cystadenoma
 - Likely do not represent true neoplasms but metaplastic reaction
 - See Chapter 15 under Laryngeal Cyst for a more complete discussion.

BENIGN NONEPITHELIAL TUMORS

- Benign mesenchymal tumors of the larynx and trachea are rare.
- In this category, tumor types include:
 - Hemangiomas
 - Benign peripheral nerve sheath tumors (neurilemoma; neurofibroma), including granular cell tumor
 - Lipoma
 - Paraganglioma
 - Leiomyoma (conventional leiomyoma, vascular leiomyoma, and epithelioid leiomyoma)
 - Chondroma
 - Rhabdomyoma
 - Giant cell tumor (osteoclastoma)
- For more complete discussion of some of these tumor types see other sections.
- This section includes discussion of the following lesions: inflammatory myofibroblastic tumor, granular cell tumor, lipoma, paraganglioma, and chondroma.

Fig. 16-8. Laryngeal inflammatory myofibroblastic tumor (IMT).

Laryngectomy specimen showing a polypoid and nodular-appearing transglottic lesion. In general, aggressive surgery is not indicated for laryngeal (or other mucosal-based) IMTs, but this is an unusual example of a multiply recurrent lesion necessitating more radical treatment.

Inflammatory Myofibroblastic Tumor (IMT) (Figs. 16-8 through 16-11)

Definition: Distinctive lesion composed of myofibroblastic and fibroblastic cells with a variable admixture of inflammatory cells, including mature lymphocytes, plasma cells, and/or eosinophils.

- Predominantly soft tissue and visceral tumor that may occur in mucosa of upper aerodigestive tract

Synonyms: Inflammatory (myofibroblastic) pseudotumor, plasma cell granuloma, plasma cell pseudotumor, pseudosarcomatous (myofibroblastic) lesions/tumors

Clinical

- IMT of upper aerodigestive tract are rare:
 - Aside from scattered case reports there are very few comprehensive studies detailing the clinicopathologic features of IMT in upper aerodigestive tract sites.
- Male predominance; contrasting to soft tissue and visceral IMT, which occur predominantly in children and young adults, IMT of the upper aerodigestive tract occur over a wide age range that includes the pediatric population but is more common in adult populations:
 - Relative to laryngeal IMT, median age of 59 years reported

Fig. 16-9. Laryngeal IMT.

Histology of (laryngeal) IMT may include **(A, B)** polypoid-appearing lesions characterized by the presence of a submucosal loosely cellular proliferation of spindle-shaped to stellate cells with variably admixed inflammatory cells; surface squamous epithelium is intact but may be ulcerated; **(C, D)** cellular proliferation is loosely arranged with a storiform to fascicular growth pattern and an edematous myxoid stroma. The overall histologic appearance can be similar to that seen in nodular fasciitis.

- In upper aerodigestive tract, IMT most commonly occur in the larynx:
 - Laryngeal sites of involvement include glottis, supraglottis, and subglottis.
 - Most common site of occurrence is the true vocal cord
 - Nonlaryngeal sites of occurrence include oral cavity, tonsil, parapharyngeal space, sinonasal tract, salivary glands, and trachea.
- Clinical presentation varies per site of occurrence:
 - Larynx: hoarseness, stridor, dysphonia, and/or a foreign body sensation in the throat; duration of symptoms range from as short as 10 days up to 4 months
 - Other aerodigestive tract sites may present as painless mass, ulcerative painful mass, nasal obstruction, epistaxis, headaches, and dysphagia.
 - Constitutional and/or systemic signs and symptoms such as fever, weight loss, pain, malaise, anemia, thrombocytosis, polyclonal hyperglobulinemia, and elevated erythrocyte sedimentation rate seen in association with soft tissue and visceral IMT are not usually a component of upper aerodigestive tract IMT. High fever, anemia and weight loss may be present.
- IMT of the upper aerodigestive tract present as solitary (isolated) lesions, typically without lesions of other upper aerodigestive tract sites or evidence of myofibroblastic lesions of other sites of the body.
- Cause of IMT in general and upper aerodigestive tract in specific is unknown:
 - No specific link to tobacco smoking, trauma (e.g., traumatic intubation), human herpesvirus-8 (HHV-8), or Epstein-Barr virus (EBV)

Pathology

Gross

- Polypoid, pedunculated, or nodular firm lesion with a smooth appearance and fleshy to firm consistency

Fig. 16-10. Myofibroblasts in IMT.

The myofibroblasts in IMT may have a varied appearance including **(A)** epithelioid or histiocytoid characterized by round to oval nuclei, prominent nucleoli, and ample basophilic to eosinophilic granular cytoplasm; **(B through D)** spindle-shaped to stellate-appearing cells with enlarged round to oblong nuclei, inapparent to prominent eosinophilic nucleoli, and abundant basophilic to eosinophilic-appearing fibrillar cytoplasm; axonal-appearing (spider-like) cells with long cytoplasmic extensions creating cells with a bipolar-to-multipolar (tadpole-like) appearance are seen; **(E)** the stroma in this example has a neurofibrillar-like appearance; GFAP staining was negative (not shown). **F**, Intranuclear eosinophilic inclusions may be seen and may represent a clue to the diagnosis of IMT.

Fig. 16-11. Immunohistochemistry of IMT.

Immunohistochemical staining of the myofibroblasts in IMT may include **(A)** vimentin; **(B)** muscle-specific actin; **(C)** smooth muscle actin; **(D)** anaplastic lymphoma kinase (ALK) reactivity including cytoplasmic staining and staining of the intranuclear inclusions (*arrowheads*).

- Range in size from 0.4 to 3 cm in greatest dimension

Histology

- Polypoid and unencapsulated characterized by the presence of a submucosal loosely cellular proliferation of spindle-shaped to stellate cells with variably admixed inflammatory cells
- Cellular proliferation loosely arranged with a storiform to fascicular growth pattern and an edematous myxoid to fibromyxoid stroma, prominent vascularity, and an inflammatory cell infiltrate composed of mature plasma cells, mature lymphocytes, eosinophils, histiocytes, and scattered polymorphonuclear leukocytes:

- Overall appearance is similar to a reactive process resembling granulation tissue and nodular fasciitis.

Myofibroblasts

- Primarily spindle-shaped or stellate with enlarged round to oblong nuclei, inapparent to prominent eosinophilic nucleoli, and abundant eosinophilic to basophilic-appearing fibrillar cytoplasm:
 - In some cases myofibroblasts may appear more epithelioid or histiocytoid, including round to oval nuclei, prominent nucleoli, and ample cytoplasm.
 - Myofibroblasts may also appear as slender axonal (spider-like) cells with elongated nuclei,

inapparent nucleoli, and long cytoplasmic extensions creating cells with a bipolar-to-multipolar (tadpole-like) appearance.

- In all their histologic forms myofibroblasts maintain a low nuclear-to-cytoplasmic ratio.
- A helpful feature may be the presence of intranuclear eosinophilic inclusions:
 - Not unique to IMT but represent a rather characteristic feature especially in the context of histologic findings associated with IMT
- Focal nuclear pleomorphism may be present; marked nuclear pleomorphism and necrosis not usually present
- Mitotic figures are present and may be numerous but atypical mitoses are not usually seen.

Stroma

- Stromal component varies from an edematous myxoid background to fibromyxoid and more fibrous (collagenized); rarely, a fibrillar appearing stroma resembling neurofibrillary matrix may be seen.
- Vascular component varies from widely dilated medium-sized vascular channels to narrow, slit-like blood vessels that can be obscured by the myofibroblasts and inflammatory cells; vascular thrombosis not present

Inflammatory Cells

- Admixture of different cell types, including mature lymphocytes, mature plasma cells, eosinophils, histiocytes, and scattered polymorphonuclear leukocytes:
 - Degree of inflammatory cell infiltrate may vary from case to case
 - Prominent mature plasma cell infiltrate may be present:
 - Previous designation for IMT was plasma cell granuloma.
 - In conjunction with sclerotic stroma as well as increased numbers of IgG4-positive plasma cell and IgG4/IgG ratio ≥ 0.10 may suggest a possible diagnosis of IgG4-related disease (see Differential Diagnosis below).

Surface Epithelium

- Surface epithelium may be intact and unremarkable to ulcerated to hyperplastic.
- Myofibroblastic proliferation may approximate surface epithelium but usually there is a separation between the myofibroblasts and surface epithelium.
- Reactive epithelial atypia may be seen but significant epithelial dysplasia (i.e., moderate to severe dysplasia), carcinoma in situ, and invasive squamous carcinoma are not present.

- Histochemistry:
 - Essentially noncontributory to the diagnosis
- Immunohistochemistry:
 - Strong diffuse cytoplasmic immunoreactivity for vimentin
 - Smooth muscle actin and/or muscle specific actin typically present but may vary from focal to diffuse
 - Desmin staining may be present.
 - CD68 may be focal in histiocytic-appearing cells.
 - Epithelial markers (cytokeratins, EMA, others) typically absent but staining for cytokeratins may be present in up to 33% of cases:
 - When present cytokeratin staining tends to be focal rather than diffuse.
 - No immunoreactivity for S100 protein, p63, HMB-45, myoglobin, myogenin (myf-4), MyoD1, CD34, CD117
 - Reactivity for anaplastic lymphoma kinase (ALK) can be seen corresponding to the presence of ALK rearrangements (see Cytogenetics later):
 - ALK reactivity is cytoplasmic.
 - Intranuclear inclusions may be ALK positive.
 - Wide range of ALK positivity reported varying from 36% to 60% of cases
 - ALK lacks specificity and sensitivity.
 - Imperfect correlation to ALK mutations
 - Different fusion partners (see Cytogenetics later) may result in different patterns of ALK immunoreactivity
- Electron microscopy:
 - IMTS show features of myofibroblastic and fibroblastic differentiation:
 - Cytoplasmic organelles include well-developed, prominent rough endoplasmic reticulum, Golgi complexes, bundles of microfilaments arranged in parallel along the long axis of the cells with focal densities (“stress fibers”), fragmented basal lamina, pinocytotic vesicles, and fibronexus junctions.
 - Fibronexus junctions represent foci on the cell surface in which intracellular myofilaments and extracellular fibronectin filaments converge.
 - Rarely, junctional complexes can be seen.
- Cytogenetics and molecular genetics:
 - In children and young adults from 50% to 70% of cases often contain clonal cytogenetic rearrangements involving chromosome band 2p23 that fuse 3' kinase region of ALK gene with various partner genes including:
 - *TPM3*, *TPM4*, *CLTC*, *RANBP2*, and *ATIC*
 - Such rearrangements are uncommon in adults >40 years of age.

- Rearrangement restricted to myofibroblastic cell component whereas inflammatory cell component is normal without gene rearrangements or expression of ALK protein
- Presence of immunohistochemical expression of the ALK C-terminal end in myofibroblastic component of IMT and low to absent detection of ALK protein in nonneoplastic myofibroblasts represent strong evidence for oncogenic activation mechanism in IMT

Differential Diagnosis

- Contact ulcer of the larynx
- Pyogenic granuloma
- Nodular fasciitis:
 - Myofibroblastic dominant proliferation
 - Typically a lesion of soft tissue but rarely may be mucosal based, originating in mucosal sites of upper aerodigestive tract, including the larynx and pharynx
 - For a more complete discussion, see Section 4, Neck.
- IgG4-related disease:
 - Although there may be some overlap in histologic findings and presence of increase IgG4 plasma cells between IgG4-related disease and IMT, these two entities have distinct clinical and pathologic findings:
 - IgG4-related disease is typically systemic but may be localized, whereas IMT are generally localized.
 - Histologic findings often seen in IgG4-related disease include obliterative phlebitis and lymphoid aggregates, features not seen in IMT.
 - IgG4-related disease is ALK negative.
 - IgG4-related disease responds to steroid treatment.
 - For a more complete discussion of IgG4-related disease see Section 6, Salivary Glands.
- Spindle cell squamous carcinoma:
 - Overtly malignant cell infiltrate that may be associated with intraepithelial dysplasia and/or invasive squamous cell carcinoma
 - Reactivity may be seen for epithelial markers (cytokeratins, others) and p63.
 - Consistently reactive for vimentin and may be reactive for mesenchymal markers including actins and desmin
 - ALK negative
 - Spindle cell squamous carcinomas, especially those with associated surface ulceration and reactive changes, may have coexisting (reactive) myofibroblasts, the latter representing part of the wound healing process.
- Myofibrosarcoma

Treatment and Prognosis

- Laryngeal IMT are treated by conservative surgical resection, including local excision by laser removal or via laryngoscopic techniques.
- Conservative resection usually curative:
 - Rarely, recurrent tumor may occur after conservative surgical resection necessitating laryngectomy.
- Targeted therapy using ALK inhibitor crizotinib has shown promising results in ALK-translocated IMT
- Recurrence rate of approximately 25% has been reported for extrapulmonary IMT.
- Rare examples of extrapulmonary (not head and neck) IMT metastasize (less than 2%):
 - May be linked to presence of *RANBP2* and round cell morphology
 - ALK-negative IMT may have higher risk of metastasis.
- Difficult to predict on the basis of pathologic features which IMTs may behave more aggressively:
 - No correlation between behavior and tumor size, nuclear atypia, mitotic activity, necrosis
 - Aggressive behavior may correlate to round cell transformation characterized by:
 - Sheets of round to epithelioid cells with vesicular nuclei, prominent nucleoli, amphophilic to eosinophilic cytoplasm, increased mitotic activity including atypical mitoses, myxoid stroma, and prominent neutrophilic infiltrate
 - Distinct nuclear membrane or perinuclear pattern of ALK staining
 - *RANBP2*-ALK fusion detected by reverse transcription polymerase chain reaction
 - To date, such changes reported in IMT located within the abdomen arising from omentum or mesentery
 - Terminology of epithelioid inflammatory myofibroblastic sarcoma suggested for this lesion conveying malignant behavior

Granular Cell Tumor

(Figs. 16-12 through 16-14)

Definition: Benign tumor of neurogenic (Schwann cell) origin characterized by lysosome-rich cells with abundant granular eosinophilic-appearing cytoplasm.

Synonyms: Granular cell myoblastoma; granular cell neuroma; granular cell schwannoma; granular cell neurofibroma; Abrikossoff tumor; granular cell schwannoma

- Two forms can occur:
 1. Mucosal granular cell tumor
 2. Congenital granular cell epulis (see Section 2, Oral Cavity, for detailed discussion)

Fig. 16-12. Endoscopic appearance of granular cell tumor.

A, Laryngeal granular cell tumor appearing as a large, solitary tan-yellow mass along the posterior aspect of the true vocal cord. **B**, Tracheal granular cell tumor appearing as a mucosal-covered nodular intraluminal protrusion.

Mucosal Granular Cell Tumor

Clinical

- Can occur in virtually any organ but most frequent sites of occurrence include:
 - Skin > tongue > breast > larynx > gastrointestinal tract > bronchus, trachea
 - Except for the larynx, granular cell tumors are more common in women than in men
 - See Section 2 on the Oral Cavity for a discussion of lingual granular cell tumor and congenital granular cell epulis.

Fig. 16-13. Granular cell tumor.

A, Histologically, granular cell tumors are characterized by the presence of round to polygonal shaped cells with round to oval, vesicular nuclei, coarse granular cytoplasm, and ill-defined cell borders. **B**, Markedly pleomorphic and hyperchromatic nuclei may be identified, which are not diagnostic for malignancy. **C**, Granular cells are immunoreactive for S100 protein, which is negative in the squamous epithelium (*arrow*).

Fig. 16-14. Pseudoepitheliomatous hyperplasia and granular cell tumor.

A, B, Pseudoepitheliomatous hyperplasia of the larynx with associated granular cell tumor. The epithelial proliferation may be misinterpreted as an invasive squamous carcinoma unless attention is paid to the presence of granular cells deep to and intermingled with the hyperplastic squamous epithelium.

- For laryngeal tumors:
 - No gender predilection; primarily affects adults in third to fifth decades of life; uncommon in children
 - Hoarseness is most common complaint.
 - Most frequently identified along the posterior aspect of the true vocal cord (posterior one third) but can also be seen in the supraglottic and subglottic areas:
 - Vocal cord > arytenoids > false cord > anterior commissure > subglottis > postcricoid area
- For tracheal tumors:
 - More common in women than in men
 - Wide age range but peak incidence is in the fourth decade
 - Symptoms include stridor and airway obstruction.
 - Most often arise in the cervical trachea
- Regardless of site, most GCTs are single lesions but multiple tumors may be found:
 - May occur synchronously or metachronously
 - Multiple granular cell tumors may occur in LEOPARD syndrome and Noonan syndrome associated with mutations in *PTPN11*.
- No known cause
- Granular cell tumors felt to be of neural (Schwann cells) origin supported by:
 - Involvement of small to medium nerves
 - S100 protein, CD57, and neuron-specific enolase positive
 - Presence of myelinated and nonmyelinated axon-like structures by ultrastructural analysis
 - Presence of residual axons in many granular cell tumors

Pathology

Gross

- Often solitary, polypoid, or sessile, tan-white to yellow, measuring from 0.3 to 3.0 cm in diameter; occasionally may have papillary or cystic areas

- Most are submucosal with an intact overlying surface epithelium, although rarely may be associated with epithelial ulceration.

Histology

NOTE: Regardless of location, histology is the same.

- Unencapsulated or poorly circumscribed subepithelial lesion with a syncytial, trabecular, or nested growth pattern
- Neoplastic cells are round to polygonal with round to oval, vesicular to hyperchromatic, centrally located small nuclei, and the presence of coarsely granular eosinophilic-appearing cytoplasm with poorly delineated cell borders.
- Cellular pleomorphism varies but usually is minimal:
 - Uncommonly markedly pleomorphic nuclei may be present.
- Mitoses and necrosis not typically present
- Occasionally, within the collagenous tissue and in the proximity of vessels, stromal histiocytes with large refractile needle-shaped bodies may be seen:
 - Referred to as angulate bodies
- Pseudoepitheliomatous hyperplasia (PEH) may be present:
 - Exuberant epithelial hyperplasia that may be associated with granular cell tumors
 - May be so exuberant as to suggest a diagnosis of invasive squamous cell carcinoma:
 - In contrast to squamous cell carcinoma, PEH typically displays no cytologic evidence of malignancy.
 - However, some examples may be histologically identical to invasive squamous cell carcinoma:
 - A diagnosis of SCC should not be rendered in the presence of granular cell tumor unless:
 - Epithelial proliferation extends beyond/below the depth of associated granular cell tumor:
 - S100 protein and cytokeratins may be needed to determine extent of the epithelial proliferation relative to the granular cell tumor.
 - Metastatic squamous cell carcinoma (locoregional, distant) is present.
- Granular cell tumor cells may involve (“invade”) nerves:
 - Does not represent an indicator of malignancy (see below for malignant granular cell tumor)
- Histochemistry:
 - Cytoplasmic granules are diastase-resistant, PAS-positive, stain with alcian blue at pH 2.5, stain red with trichrome, and vary in size from being minute to as large as red blood cells.
 - Angulate bodies are intensely PAS positive.
- Immunohistochemistry:
 - S100 protein, calretinin, CD57 (Leu-7) positive
 - Strongly CD68 (KP-1) positive as well as alpha-1-antitrypsin and alpha-1-antichymotrypsin
 - Laminin and collagen type 4 are positive, highlighting basement membranes around groups of tumor cells.
 - Additional consistent but nonspecific staining seen for inhibin alpha-subunit and protein gene product 9.5:
 - Significance of inhibin expression with regard to cell differentiation and pathogenesis is unclear.
 - Proliferative activity as seen by Ki-67 reactivity is low.
 - Negative for cytokeratins, neurofilament protein, and glial fibrillary acidic protein
 - Interstitial cells with angulate bodies are CD68 positive and S100 protein negative.
- Electron microscopy:
 - Characterized by presence of numerous intracellular large granules (secondary lysosomes) consisting of membrane-bound, autophagic vacuoles containing mitochondria, rough endoplasmic reticulum, myelin figures, and myelinated and nonmyelinated axon-like structures
 - Interstitial cells contain membrane-bound structures with parallel arrays of microtubules representing angulated bodies as well as microfilaments and lipid material.

Differential Diagnosis

- Rhabdomyoma
- Invasive squamous cell carcinoma as a result of the PEH
- Alveolar soft part sarcoma
- Malignant granular cell tumor:
 - Rare neoplasms accounting for approximately 1% of all granular cell tumors
 - Clinically are similar to benign granular cell tumors except that they do not occur in newborns or children
 - Usually measure >4.0 cm in diameter and tend to occur in the extremities
 - Histologically, a diagnosis of malignancy can be made in the presence of three of the following criteria:
 - Necrosis
 - Spindle-shaped cells
 - Increased nuclear-to-cytoplasmic ratio
 - Vesicular nuclei with prominent nucleoli
 - Pleomorphism
 - Increased mitotic activity (greater than two mitoses per 10 high-power fields)
 - Any granular cell tumor in which one or two of the above criteria are found can be referred to as atypical.

- Transition from benign granular cell tumor to malignant granular cell tumor is frequently apparent.
- Immunohistochemical staining similar to that of benign granular cell tumors except:
 - CEA reactivity reported, significance of which is not known
 - Increase proliferation rate from 10% to 50% by Ki67 (MIB1) staining
 - Extensive p53 staining in up to 70% of cases
- Differential diagnosis includes alveolar soft part sarcoma and paraganglioma.
- Surgery is the preferred treatment (wide en bloc excision); radio- and chemotherapy are ineffective.
- Metastasize via lymphatics and blood vessels (lymph nodes, lung, liver, and bone)

Treatment and Prognosis

- Conservative but complete surgical excision is considered curative:
 - Small tumors can be excised endoscopically.
- Granular cell tumors are radioresistant.
- Local recurrence may occur in a minority of patients (less than 10%):
 - Recurrent tumor may represent a new primary lesion in patients with multifocal disease.

Laryngeal Paraganglioma

(Figs. 16-15 and 16-16)

Definition: Benign neoplasm arising from the extra-adrenal neural crest-derived paraganglia specifically located in the larynx, and believed to arise from the superior and inferior laryngeal paraganglia.

Synonym: Glomus tumor

Histoanatomy

- Laryngeal paraganglia are microscopic structures with variable anatomic distribution in relation to cricoid and thyroid cartilages.
 - Most are paired structures located in superior and inferior locations in lateral larynx.
 - Sometimes found immediately adjacent to thyroid gland or within capsule of thyroid gland
 - Described in relation to laryngeal recurrent nerve
- Physiologic role of laryngeal paraganglia unknown

Clinical

- Uncommon laryngeal tumor
- More common in women than in men; wide age range but most common in the fifth decade of life
- Vast majority (greater than 80%) predilect to the supraglottic larynx with the aryepiglottic fold and false vocal cord representing the most common sites of occurrence.

Fig. 16-15. Laryngeal paraganglioma.

A and B, The tumor is located wholly within the submucosa showing characteristic organoid or cell nest ("zellballen") growth with the cell nests separated by fibrovascular stroma. **C,** Cells nests are composed predominantly of chief cells with uniform round to oval nuclei, dispersed chromatin pattern, and abundant eosinophilic, granular, or vacuolated cytoplasm; sustentacular cells situated at the periphery of the cell nests are difficult, if not impossible, to identify by light microscopy.

Fig. 16-16. Special stains in paraganglioma.

Special stains that can be seen in (laryngeal) paragangliomas may include **(A)** argyrophilic (Churukian-Schenk) positive intracytoplasmic granules; **(B)** dedicated chromogranin reactivity to the chief cells (*left*) and dedicated S100 protein to the sustentacular cells (*right*).

- Clinical presentation includes hoarseness, dysphagia, dyspnea, and stridor.
- Generally are not hormonally (functionally) active, although exceptional cases may be functional.
- Rarely may be multicentric with other head and neck paragangliomas
- Radiology:
 - CT: enhancing mass
 - MRI: intermediate signal intensity on T1-weighted image and high signal intensity on T2-weighted image

Pathology

Gross

- Submucosal tumors ranging in size from 0.5 to 6.0 cm

Histology

- Located in submucosa without involvement of overlying intact epithelium

- Identical to paragangliomas of more usual sites:
 - Histologic hallmark is the presence of a cell nest or “Zellballen” pattern cell nest characteristic of paragangliomas.
 - Stroma surrounding and separating the nests is composed of a prominent fibrovascular tissue
 - Neoplasm is composed predominantly of chief cells, which are round or oval with uniform nuclei, dispersed chromatin pattern, and abundant eosinophilic, granular, or vacuolated cytoplasm
 - Sustentacular cells difficult, if not impossible, to identify by light microscopy:
 - These cells represent modified Schwann cells.
 - Are located at the periphery of cell nests
 - Appear as spindle-shaped, basophilic-appearing cells
- Glandular or alveolar differentiation is not seen.
- Histochemistry:
 - Reticulin staining may better delineate the cell nest growth pattern with staining of the fibrovascular cores surrounding the neoplastic nests
 - Tumor cells are argyrophilic (Churukian-Schenk)
 - Argentaffin (Fontana-Masson), mucicarmine, and periodic acid Schiff stains are negative.
- Immunohistochemistry:
 - Chief cells:
 - Chromogranin, synaptophysin, CD56, neuron-specific enolase, neurofilaments, and a variety of peptides positive; GATA3 positive (nuclear)
 - May also be S100 protein positive
 - Sustentacular cells:
 - S100 protein positive, Sox10 positive
 - Vimentin is variably reactive in chief cells and sustentacular cells
 - In general, epithelial markers, including cytokeratins and p63, are negative:
 - Rare examples of cytokeratin-reactive paragangliomas are reported.
 - Melanocytic markers (HMB45, melan-A, tyrosinase, MITF, Sox10) negative
 - Myogenic markers (desmin, myogenin, others) negative
- Electron microscopy:
 - Abundant neurosecretory granules (100 to 250 nm)
 - Cellular junctional complexes are rarely (if ever) seen.

Differential Diagnosis

- Neuroendocrine carcinomas including carcinoid tumor and atypical carcinoid (see [Box 16-5](#) and [Table 16-6](#))

Treatment and Prognosis

- Surgery is the preferred treatment and is curative.
- Malignant paragangliomas reported in the literature more likely represent neuroendocrine carcinoma

Chondroma (Fig. 16-17)

Definition: Benign tumor of mature hyaline cartilage.

Clinical

- Cartilaginous neoplasms of the head and neck are uncommon, and those of the larynx are rare:
 - Laryngeal chondrosarcomas are more common than chondromas.
- Most common sites of occurrence of head and neck chondromas include:
 - Sinonasal tract
 - Less common sites include maxilla and mandible, larynx, palate, pharynx, nasopharynx, and ear.
- In the larynx, chondromas may originate from posterior lamina of cricoid cartilage and thyroid cartilage and less often from epiglottis and arytenoids.
 - May arise in soft tissues of the true vocal cords (Reinke space)
- May be incidentally identified or cause hoarseness:
 - A clinically significant cartilaginous tumor of the larynx is most likely a chondrosarcoma.
- Radiology:
 - Discrete soft tissue mass contiguous with its laryngeal cartilaginous origin
 - Coarse calcifications and ossification may be seen.

- Involvement of Reinke space most probably represents a metaplastic rather than a true neoplastic process with derivation from the vocal cord ligament.

Pathology

Gross

- Lobulated, firm to hard, blue-gray, submucosal mass seldom measuring greater than 1 cm:
 - Although laryngeal chondromas seldom attain sizes greater than 1 cm, occasionally they may grow to sizes up to 4 cm.

Histology

- Submucosal lobulated or nodular growth(s) composed of chondrocytes recapitulating the normal histology of cartilage.
- Absence of cellular pleomorphism, binucleate chondrocytes, or mitotic activity
- Immunohistochemistry:
 - S100 protein positive
 - Podoplanin (D2-40) positive

Differential Diagnosis

- Cartilaginous hamartoma
- Chondrosarcoma (see later in chapter)

Treatment and Prognosis

- Conservative but wide surgical excision including an adequate margin of normal tissue is the preferred treatment:
- Surgical resection is curative.

Fig. 16-17. Laryngeal chondroma.

A, Submucosal cartilaginous nodules with intact overlying squamous epithelium. **B**, At high magnification the chondrocytes are bland in appearance, lacking significant nuclear pleomorphism, binucleate chondrocytes, or mitotic activity as may be seen in low-grade chondrosarcomas.

- Recurrences are uncommon and according to most authorities do not occur in association with laryngeal chondromas.
- Recurrent chondromas of the larynx should prompt a diagnosis of a low-grade chondrosarcoma.

Lipoma (Fig. 16-18)

Definition: Benign tumor of mature adipocytes.

Clinical

- In the head and neck, most often occur in the neck region (see Section 4, Neck, for more complete discussion)
- Rare tumor of larynx (and hypopharynx)
- More common in men than in women; adult ages usually sixth decade and older
- Solitary tumors often arising in the supraglottic larynx or project into the larynx from a hypopharyngeal mass:

Fig. 16-18. Laryngeal lipoma.

A, B, Circumscribed submucosal tumor composed of mature adipocytes lacking evidence of cytologic atypia.

- Laryngeal sites of occurrence include aryepiglottic fold, vestibular fold, and epiglottis.
- Symptoms include dysphagia, dyspnea, acute airway obstruction, hoarseness, dysphonia, and a lump in the throat.
- Radiology:
 - CT scan: low attenuation mass:
 - Adipose tissue is the only soft tissue that has a density less than water (zero or negative Hounsfield units) so that CT scan reveals extent of the mass and also its lipomatous nature.
- No known cause:
 - Rare cases reported in association with symmetric lipomatosis (Madelung disease or Launois-Bensaude syndrome)

Pathology

Gross

- Sessile to pedunculated mass measuring from a few millimeters to 6.0 cm in greatest dimension

Histology

- Encapsulated tumor of mature adipose tissue (adipocytes):
 - Adipocytes are uniform, varying slightly in size and shape.
 - Atypical adipocytes and/or lipoblasts are not identified.
- Richly vascularized but vascularity may be difficult to appreciate due to compression by distended adipocytes.
- Secondary changes may include hemorrhage, calcification, cyst formation, fat necrosis, and infarction.
- Metaplastic bone and cartilage may be identified.
- Laryngeal (and hypopharyngeal) lipomas may include:
 - Lipomas with prominent myxoid stroma (myxolipoma) or prominent fibrous tissue component (fibrolipoma)
 - Intramuscular lipomas:
 - Also referred to as infiltrating lipoma
 - Characterized by the presence of mature adipocytes infiltrating skeletal muscle
 - Spindle cell lipoma:
 - Characterized by mature adipocytes admixed with uniform, small spindle cells, and eosinophilic collagen bundles set in a myxoid matrix with a vascular pattern varying from inconspicuous to prominent
 - Mast cells can be seen in association with the spindle cells.
 - Other types of lipomas including angiolipoma, pleomorphic lipoma, angiomyolipoma, and lipoblastoma not reported in these sites

- Immunohistochemistry (not needed for the diagnosis):
 - Adipocytes are S100 protein positive.
 - CD34 positive in spindle cell lipomas
 - MDM2 and CDK4 negative
- Hibernoma (benign tumors of brown fat)
 - Rare examples reported to occur in the larynx
- For spindle cell lipoma:
 - Various spindle cell neoplasms of these sites

Treatment and Prognosis

- Surgery is curative.
- May rarely recur:
 - May be a function of inadequate excision
 - Presence of recurrence should raise diagnosis of well-differentiated liposarcoma:
 - Does not represent transformation from a lipoma but initial lesion was a liposarcoma that went undiagnosed due to overall bland morphology lacking overt evidence of malignancy
 - In this setting staining for MDM2 and CDK4 may prove useful and diagnostic.

MALIGNANT NEOPLASMS OF THE LARYNX AND HYPOPHARYNX

GENERAL CONSIDERATIONS

- Squamous cell carcinoma or a variant thereof is most common malignant neoplasm of the larynx
- See Section 2, Oral Cavity, for a more complete discussion of the following topics related to head and neck squamous cell carcinoma (HNSCC):
 - Mutagen sensitivity
 - “Field cancerization”
 - Second primary malignancy
 - Genetics of HNSCC
 - Prognostic indicators, including:
 - Status of the surgical resection margins
 - Nodal metastasis
 - Lymph-vascular invasion
 - Invasion of soft tissue structures including nerves and cartilage
 - Distant metastasis
 - Multiple primary malignancies (second malignancy)
 - Host immunologic response

neoplasia (SIN); laryngeal intraepithelial lesion (LIN); laryngeal intraepithelial lesion (LIL); simple hyperplasia; basal/parabasal hyperplasia; atypical hyperplasia

- Recommended WHO terminology includes mild, moderate, and severe dysplasia and carcinoma in situ (Table 16-2).

Clinical

- More common in men than in women; generally limited to the adult population with a mean age at diagnosis in the sixth decade of life
- May occur anywhere in the larynx but mainly identified along the true vocal cord:
 - Typically is a unilateral lesion but may be bilateral in up to 30% of cases
- Most frequent symptom is hoarseness.
- May appear white (leukoplakia), red (erythroplakia), or mixed red and white (speckled leukoplakia):
 - See Section 2, Oral Cavity, for more complete discussion on leukoplakic and erythroplakic lesions.
- Causes may include:
 - Tobacco smoking (most common) and excess alcohol use:
 - Alcohol potentiates the effect of tobacco smoking.
 - Risk of developing dysplastic lesions increases with duration of smoking and/or alcohol use.
 - Chronic infections, including fungal infection
 - Less commonly secondary to voice abuse, environmental/industrial exposure, and vitamin A deficiency
 - Role of human papillomavirus in development of intraepithelial dysplasia of the larynx remains unproven:

LARYNGEAL EPITHELIAL DYSPLASIA

Keratinizing and Nonkeratinizing Dysplasia (Figs. 16-19 through 16-22)

Definition: Alteration in a malignant direction in the appearance of epithelial cells with an increased likelihood to progress to squamous cell carcinoma.

Synonyms: Keratosis with atypia; atypia; mild dysplasia; moderate dysplasia; severe dysplasia; squamous intraepithelial lesion (SIL); squamous intraepithelial

Fig. 16-19. Laryngeal nonkeratinizing dysplasia.

The grading in these dysplastic lesions is similar to that of the uterine cervix and includes **(A)** mild dysplasia when the dysplastic changes are limited to the lower third of the surface epithelium; **(B)** moderate dysplasia when the dysplastic changes involve two thirds of the surface epithelium; and **(C)** severe dysplasia (carcinoma in situ) when the dysplastic changes involve the entire surface epithelium without violation of the basement membrane.

Fig. 16-20. Laryngeal keratinizing mild dysplasia.

Laryngeal keratinizing mild dysplasia (low-grade squamous intraepithelial lesion) showing squamous epithelium with associated keratosis and dysplastic cytologic changes limited to the basal zone with relatively flat-appearing epithelium without associated elongated and downwardly extending rete ridges. Mitotic figures (*arrowheads*) are seen at the junction (more or less) of the lower and mid-epithelial layers.

Fig. 16-21. Laryngeal keratinizing moderate dysplasia.

Laryngeal keratinizing moderate dysplasia (high-grade squamous intraepithelial lesion) showing squamous epithelium with associated keratosis and dysplastic cytologic changes involving at least two thirds of the thickness of the epithelium with relatively flat to widened and/or slightly elongated and downwardly extending rete pegs. In these images there is still maturation of the most superficial layer of the epithelium. However, given a shared risk to progression to invasive carcinoma with keratinizing severe dysplasia, a classification that includes keratinizing moderate and severe dysplasias within the category of high-grade squamous intraepithelial lesion appears justified.

TABLE 16-2 Classification Schemes for Epithelial Precursor Lesions

WHO*	SIN	Ljubljana	Modified Ljubljana	Two-Tiered
Mild dysplasia	SIN 1	Basal/parabasal cell hyperplasia	LGSIL	LGSIL
Moderate dysplasia	SIN 2	Atypical hyperplasia	HGSIL	HGSIL
Severe dysplasia	SIN 3	Atypical hyperplasia	HGSIL	HGSIL
CIS	SIN 3	CIS	CIS	HGSIL

CIS, Carcinoma in situ; *HGSIL*, low-grade squamous intraepithelial lesion; *LGSIL*, low-grade squamous intraepithelial lesion; *SIN*, squamous intraepithelial neoplasia; *WHO*, World Health Organization.

*Currently recommended classification scheme.

Fig. 16-22. Laryngeal keratinizing severe dysplasia.

A through **C**, Laryngeal keratinizing severe dysplasia tantamount to carcinoma in situ (high-grade squamous intraepithelial lesion) including architectural alterations with widening and elongated and downwardly growing rete ridges coupled to cytomorphic changes. All of these examples include an absence of full-thickness intraepithelial dysplasia, thereby falling short of the classic definition for carcinoma in situ. Nevertheless, these lesions all merit designation as keratinizing severe dysplasia tantamount to carcinoma in situ as the risk of progression to invasive carcinoma is similar to that of “classic” carcinoma in situ. Further, such lesions can progress to invasive carcinoma in the absence of full-thickness intraepithelial dysplasia. **D**, Paradoxical maturation characterized by abnormal keratinization in the basal zone; associated high-grade dysplastic cytomorphic features are present.

Fig. 16-22, cont'd

E, Example of laryngeal invasive carcinoma originating from dysplastic changes limited to the basal zone epithelium ("drop off" carcinoma) without full thickness intraepithelial dysplasia.

- High-risk HPV uncommon finding in head and neck squamous cell carcinoma from patients who have history of tobacco or alcohol use
- Low-risk HPV not associated with such cases
- Prevalence of HPV in precursor lesions (i.e., dysplasia) reported in approximately 12% of cases
- HPV DNA reported in 12% to 25% of normal (clinically and histologically) larynges

Pathology

Gross

- Localized, circumscribed flat, or papillary area with white (leukoplakic), red (erythroplakic), or gray appearance

Histology (Box 16-2)

- Histomorphologic changes can be separated into architectural abnormalities and cellular abnormalities and include proliferation of immature or "uncommitted" cells with process beginning in basal and parabasal area:

BOX 16-2 Histomorphologic Changes Associated with Dysplasia

Architectural Abnormalities

- Irregular epithelial stratification with elongated rete ridges extending in a downward fashion into submucosa
- Loss of maturation with increased cellularity in the superficial epithelium:
 - Normally in mature squamous epithelium there is a decrease in the cellularity from the basal zone toward the keratinizing layers.
- Crowding of cells with loss of polarity especially in the basal zone
- Increased mitotic activity, especially away from the basal zone involving the mid- and upper (superficial) portions of the surface epithelium:
 - May include atypical forms
- Abnormal keratosis (dyskeratosis) and paradoxical maturation:
 - Occurs in individual cells
 - Keratin pearls in elongated rete ridges

Cellular Abnormalities

- Abnormal variation in nuclear size (anisonucleosis)
- Abnormal variation in the nuclear shape (nuclear pleomorphism)
- Increase nuclear size relative to cytoplasm (increased nuclear-to-cytoplasmic ratio)
- Nuclear hyperchromasia with irregularities in nuclear contour
- Prominent nucleoli (not unique to dysplasia may be seen in reactive or reparative processes)

- Architectural abnormalities:
 - Irregular epithelial stratification with elongated rete ridges extending in a downward fashion into submucosa
 - Loss of maturation with increased cellularity in the superficial epithelium:
 - Normally in mature squamous epithelium there is a decrease in the cellularity from the basal zone toward the keratinizing layers
 - Paradoxical maturation (abnormal keratinization or keratin pearl formation in the basal zone)
 - Crowding of cells with loss of polarity especially in the basal zone
 - Increased mitotic activity, especially away from the basal zone involving the mid- and upper (superficial) portions of the surface epithelium:
 - May include atypical forms
 - Abnormal keratosis (dyskeratosis):
 - Occurs in individual cells
 - Keratin pearls in elongated rete pegs
- Cellular abnormalities:
 - Abnormal variation in nuclear size (anisonucleosis)
 - Abnormal variation in the nuclear shape (nuclear pleomorphism)

- Increased nuclear size relative to cytoplasm (increased nuclear-to-cytoplasmic ratio)
- Nuclear hyperchromasia with irregularities in nuclear contour
- Prominent nucleoli (not unique to dysplasia and may be seen in a reactive or reparative process)
- Histomorphologic evaluation for dysplasia is primarily predicated on the cellular abnormalities but also include architectural abnormalities especially in relationship to keratinizing dysplastic lesions.

Grading of Epithelial Dysplasia

- Grading of upper aerodigestive tract intraepithelial dysplasias is controversial and fraught with subjectivity especially for keratinizing dysplasias.
- Variety of grading schemes proposed (see Table 16-2) but at present the recommended classification scheme is three-tiered system of grading intraepithelial dysplasias advocated by the World Health Organization to include:
 - Mild dysplasia (grade I):
 - Dysplasia limited to the lower portions or inner third of the epithelium (basal zone dysplasia)
 - Moderate dysplasia (grade II):
 - Dysplasia involves up to two thirds of the thickness of the epithelium.
 - Severe dysplasia (grade III):
 - Dysplasia involves from two thirds to almost complete thickness of the epithelium.
 - Carcinoma in situ is subsumed within this grade.
- Two-tiered system of grading intraepithelial dysplasias (see Table 16-2) is advocated to include:
 - Low-grade squamous intraepithelial dysplasia includes mild dysplasia.
 - High-grade squamous intraepithelial dysplasia includes moderate and severe dysplasia/carcinoma in situ.
 - More reproducible with greater consensus among pathologists than three-tiered system:
 - Subject of Hershey Consensus Conference (unpublished data)
 - No statistical differences in risk of progression to invasive carcinoma between moderate and severe dysplasia justifying “lumping” these two lesions within a single category similar to Bethesda classification of uterine cervical squamous intraepithelial lesions
- Paradigm for grading epithelial dysplasia is one used for uterine cervix referred to as “classic” or nonkeratinizing dysplasia:
 - Absent keratosis
 - Increasing gradations of dysplasia include mild (grade I), moderate (grade II), and severe (grade III), with the latter representing full-thickness replacement of the squamous epithelium by atypical, small, immature basaloid cells and referred to as carcinoma in situ (CIS)
- Grading scheme is reproducible and is clinically useful.
- “Classic” or nonkeratinizing dysplasia is uncommon in the upper aerodigestive tract, especially in the laryngeal glottis.
- Majority of the upper aerodigestive tract lesions, especially larynx and oral cavity (see Section 2), are keratinizing dysplasias:
 - Alterations occur in the presence of surface keratinization.
 - Criteria for evaluating keratinizing dysplasias are less defined and diagnosis of severe keratinizing intraepithelial dysplasia remains controversial.
 - Definition of severe dysplasia in the setting of keratosis, especially in the laryngeal glottis, is broader than the highly reproducible pattern seen in the uterine cervix and includes a microscopically heterogeneous group of lesions.
 - In the setting of keratinizing dysplasia in which surface maturation is retained with only partial replacement of the epithelium by atypical cells, severe dysplasia includes those lesions in which epithelial alterations are so severe that there would be a high probability for the progression to an invasive carcinoma if left untreated.
 - Severe dysplasia shows presence of aberrant cell maturation with dyskeratotic cells and mitotic figures with or without atypical forms above the basal zone.
 - In the evaluation of upper aerodigestive tract dysplasia, the presence of surface keratinization is not significant; however, finding dyskeratotic cells represents an important clue to the presence of significant dysplasia.
 - In conjunction with the cytomorphologic changes, architectural alterations also factor into the evaluation and the presence of elongated and irregular-appearing rete ridges extending downward into the submucosa assists in determining the degree of dysplasia in the setting of a keratotic proliferation.
- Carcinoma in situ (CIS) as applied to the uterine cervix by histologic definition requires loss of maturation of squamous epithelium:
 - By this definition keratotic dysplastic lesions cannot be CIS owing to the presence of maturation of the squamous epithelium.
 - Use of the specific term CIS relative to keratinizing dysplasias has been questioned and is likely inappropriate in this setting.
 - More appropriate designation that of severe keratinizing dysplasia tantamount to CIS

- Histopathologic interpretation and grading of epithelial dysplastic changes in the upper aerodigestive tract are imprecise and subjective:
 - Given the complexities in the issues relative to UADT intraepithelial lesions, confusion and misunderstandings may occur between the clinician and the pathologist that may result in inappropriate management of the patient.
 - Uniformity in terminology is desirable so that there is a correlation between the pathologic diagnosis and the clinical import of that diagnosis.
 - In an attempt to standardize the terminology of upper aerodigestive tract, intraepithelial lesions using a grading system akin to that of the cervical mucosa, including terminology of squamous intraepithelial neoplasia (SIN) with SIN I equivalent to mild dysplasia, SIN II to moderate dysplasia, and SIN III to severe dysplasia
 - Similar gradations but using terminology of laryngeal intraepithelial neoplasia (LIN) and laryngeal intraepithelial lesion (LIL) have been proposed.
 - Ljubljana classification (see Table 16-2) of laryngeal precancerous lesions was proposed; in this system the terms used include:
 - Simple hyperplasia (i.e., keratosis without atypia)
 - Abnormal hyperplasia (i.e., keratosis with atypia)
 - Atypical hyperplasia (i.e., severe dysplasia)
 - Carcinoma in situ
 - More recently amended Ljubljana classification (see Table 16-2) proposed dividing squamous intraepithelial lesions (SIL) into low-grade, high-grade, and carcinoma in situ (CIS):
 - Low-grade SIL is considered to be most often benign, with low malignant potential, characterized by a spectrum of morphologic changes ranging from a simple hyperplastic process with retention of the basal layer and an increased prickle cell layer, to augmentation of basal and parabasal cells occupying up to the lower half of the epithelium, with the upper part remaining unchanged, containing regular prickle cells.
 - High-grade SIL considered to be a potentially premalignant lesion with $\geq 12\%$ of patients subsequently developing malignancy is morphologically characterized by a spectrum of changes, including augmentation of immature epithelial cells, which occupy the lower half or more of the epithelial thickness.
 - Carcinoma in situ reserved for lesions showing features of conventional carcinoma, e.g., structural and cellular abnormalities but without invasion (intraepithelial carcinoma)
 - Facilitates better interobserver agreement than previous systems, and retrospective follow-up study demonstrated highly significant difference in risk of malignant progression between low-grade and high-grade SILs
- At present preferred grading for dysplastic epithelial alterations of the upper aerodigestive tract include mild, moderate, and severe dysplasia depending on the degree and extent of cellular and maturation alterations that are present:
 - Histologic grading is evolving and as previously indicated a two-tiered system to include low grade (mild dysplasia) and high grade (moderate dysplasia and severe dysplasia/CIS) for upper aerodigestive tract epithelial dysplastic lesions may be adopted.
- Risk of progression to invasive carcinoma
 - End point for the grading of dysplasia is to convey to the clinician what is the potential biologic behavior of a given epithelial lesion.
 - Keratotic epithelium without dysplasia carries a very low risk of developing subsequent carcinoma, with reported incidences of 1% to 5%.
 - In contrast, keratotic epithelium with dysplasia is associated with an increased risk for the subsequent progression or development of premalignant or overtly carcinomatous changes varying from 11% to 18% of cases.
 - This risk of malignant transformation represents an increase of three to five times as compared with carcinoma arising in keratotic lesions without atypia.
 - The risk for progression to invasive carcinoma in lesions diagnosed as keratosis with atypia varies depending on the degree of atypia/dysplasia:
 - For mild dysplasia: approximately 6%
 - For moderate dysplasia: approximately 23%
 - For severe dysplasia: approximately 28%
 - For those lesions that progress to invasive carcinoma the average latency period from the diagnosis of keratosis with atypia to invasive carcinoma is 3.8 years
 - Histologic features seen in those dysplasias progressing to invasive carcinoma as compared with those lesions that remain stable and do not progress include:
 - Increased mitotic activity in the middle and upper portions of the epithelium
 - Presence of atypical mitoses
 - Moderate to severe nuclear pleomorphism
 - Proliferation of small uncommitted cells above the basal zone or lower third of the mucosa

- Another important point to recognize is the clinical concern attached to a diagnosis of severe keratinizing intraepithelial neoplasia:
 - Clinical concern is due to fact severe dysplasia is often multifocal and frequently occurs adjacent to or near synchronous foci of invasive carcinoma
 - This form of dysplasia has a rate of progression to invasive carcinoma that is greater than that of “classic” carcinoma in situ in setting or non-keratinizing dysplasia.
 - A diagnosis of severe dysplasia requires therapeutic intervention, as well as clinical evaluation of the entire upper aerodigestive tract to exclude the possible presence of additional foci of dysplasia or carcinoma.
- Immunohistochemistry:
 - No known reliable markers to assist in diagnosis and differential diagnosis
 - Increased proliferation rates in suprabasal epithelium by Ki67 (MIB1) staining seen in higher grade dysplasias
 - Increased p53 immunoreactivity seen in higher grade dysplasias
 - p16 not a reliable marker in determining presence or absence of dysplasia in the larynx:
 - Predominance of keratinizing dysplasia in larynx (often etiologically linked to tobacco and alcohol use) not associated with transcriptionally active virus:
 - p16 and p21 immunohistochemistry may be present in laryngeal keratinizing dysplasia but do not correlate to the presence of transcriptionally active HPV.
 - p16 should not be used as the definitive surrogate marker of HPV-driven tumors in the larynx.
- Cytogenetics and molecular genetics:
 - Loss of heterozygosity at 3p21, 5q21, 9p21, 17p13 more likely to progress to invasive carcinoma
 - Tumor suppressor gene p53 implicated in head and neck carcinogenesis:
 - p53 mutations found in >50% of invasive head and neck squamous cell carcinoma

Differential Diagnosis

- Reactive epithelial changes
- Infectious disease(s)
- Microinvasive carcinoma:
 - Diagnosis of microinvasive carcinoma should be reserved for cases in which there is definitive evidence of dissociated squamous cells at the epithelial-to-stromal interface with invasion of the lamina propria; see later in section for more complete discussion.

Treatment and Prognosis

- Excisional biopsy by vocal cord stripping or by forceps is preferred treatment.
- Close follow-up of the patient is advocated; if clinically warranted, rebiopsy may be necessary and should be performed months after any procedure to allow adequate healing and fewer surgery-associated pathologic changes that may hamper the histologic evaluation and/or obscure a neoplastic process.
- Cessation of contributing risk factors should be undertaken:
 - In general, mild and moderate dysplasias are felt to be potentially reversible alterations.
 - Circumstantial evidence supports the idea that preinvasive dysplasias are potentially reversible after cessation or removal of an instigating factor such as tobacco use.
 - Problem of predicting the malignant potential of a dysplastic lesion is greatest in cases of moderate dysplasia:
 - Virtually impossible to differentiate the moderately dysplastic lesions that are reversible from those that represent the earliest forms of neoplastic transformation
 - Diagnosis of moderate dysplasia should engender enough concern to the clinician to warrant close patient follow-up.
 - Recurrence or persistence of this dysplasia may be indicative of malignant transformation.
 - Determination of whether a mild to moderate dysplasia is reactive or neoplastic, although a desirable goal, is not always achievable; the clinically abnormal lesions that show limited cytologic and architectural abnormalities falling under the designation of reactive atypias or hyperplastic lesions represent reversible changes that rarely, if ever, progress to carcinoma:
 - These lesions are responsive to conservative management.
 - Uterine cervical moderate dysplasia (cervical intraepithelial neoplasia II) and severe dysplasia (cervical intraepithelial neoplasia III) are currently lumped in the category of high-grade squamous intraepithelial lesion (HGSIL).
 - Risk of progression to invasive carcinoma relative to upper aerodigestive tract moderate dysplasia (approximately 23%) and severe dysplasia (approximately 28%) is not statistically significant.
 - To date, grouping of upper aerodigestive tract keratinizing moderate and severe dysplasia into a single category as high-grade squamous intraepithelial lesion similar to the uterine cervix has not been adopted but may be the

recommended grading scheme in the near future to include:

- Low-grade squamous intraepithelial lesion/neoplasia for mild dysplasia
- High-grade squamous intraepithelial lesion/neoplasia for moderate and severe dysplasias

CARCINOMA IN SITU (CIS)

(Fig. 16-23)

Definition: Classically defined as cellular dysplasia involving the entire thickness of the mucosa without compromise of the basement membrane:

Fig. 16-23. Laryngeal “classic” carcinoma in situ (CIS).

A and **B**, Nonkeratinizing epithelium showing full-thickness intraepithelial dysplasia. **C**, CIS with extension to subadjacent minor salivary gland, a finding that still constitutes CIS and not invasive carcinoma.

- Dysplasia may extend into adjacent seromucous glands and is still considered as an in situ lesion.

Clinical

- Represents approximately 1% to 13% of all laryngeal carcinomas
- More common in men than in women; most frequently seen in the sixth to seventh decades of life
- Can occur anywhere in the larynx but most often involves the anterior one third of one or both true vocal cords:
 - May involve the entire cord
 - May be bilateral
 - Frequently associated with an invasive squamous cell carcinoma either lying adjacent to or remote from one another
 - May exist as an isolated lesion unrelated to invasive carcinoma
 - Multifocal areas can occur.
- Hoarseness is most frequent presenting complaint.
- CIS may be associated with invasive carcinoma:
 - Invasive carcinoma may occur in association with CIS or may be separate from CIS.
 - Clinically, evaluation is advised to exclude the possible presence of invasive carcinoma.
- Risk factors include:
 - Tobacco smoking (most common) and excess alcohol use:
 - Alcohol potentiates the effect of tobacco smoking.
 - Risk of developing dysplastic lesions increases with duration of smoking and/or alcohol use
 - Role of human papillomavirus in development of carcinoma in situ of the head and neck (other than oropharynx) not proven
- Presence of mitoses in all layers of the mucosa:
 - May include normal and abnormal forms
- Keratosis and dyskeratosis may be present.
- In presence of a diagnosis of CIS, the pathologist should liberally section the specimen to rule out the presence of an invasive squamous cell carcinoma.
- As previously noted under epithelial precursor lesions (see above), classic carcinoma in situ histologically defined as full-thickness intraepithelial dysplasia is uncommon relative to upper aerodigestive tract intraepithelial keratinizing dysplasias; CIS typically occur in nonkeratinizing dysplasia, which is an uncommon lesion in mucosal sites of the upper aerodigestive tract, especially the larynx and oral cavity:
 - Keratinizing dysplasias are much more common, and in such lesions full-thickness intraepithelial dysplasia (i.e., classically defined CIS) is uncommon and is not a prerequisite for development of invasive carcinoma.
 - In setting of keratinizing dysplasia, marked dysplastic alterations may be restricted to basal zone epithelium only, from which invasive carcinoma may develop.
 - Given such findings, use of diagnostic terms such as “keratinizing severe dysplasia, tantamount to carcinoma in situ” conveys to the surgeon alterations in a lesion that will behave similarly to carcinoma in situ (i.e., irreversible and likely to progress to invasive carcinoma unless adequately treated).
- Immunohistochemistry:
 - No known reliable markers to assist in diagnosis and differential diagnosis
 - Increased proliferation rates in suprabasal epithelium by Ki67 (MIB1) staining seen in higher-grade dysplasias
 - Increased p53 immunoreactivity seen in higher-grade dysplasias
 - p16 not a reliable marker in determining presence or absence of dysplasia in the larynx:
 - Predominance of keratinizing dysplasia in larynx (often etiologically linked to tobacco and alcohol use) not associated with transcriptionally active virus:
 - p16 and p21 immunohistochemistry may be present in laryngeal keratinizing dysplasia but does not correlate to the presence of transcriptionally active HPV.
 - p16 should not be used as definitive surrogate marker of HPV-driven tumors in the larynx.

Pathology

Gross

- Circumscribed or diffuse lesion with a white, red, or gray color and a smooth to granular appearance

Histology

- Dysplastic process involves the entire thickness of the squamous epithelium without violation of the basement membrane:
 - Extension into adjacent seromucous glands (particularly in the region of the anterior true vocal cord) may occur and does not constitute invasion.
- Squamous epithelium may or may not be thickened.
- Cytomorphologic changes include:
 - Increased nuclear pleomorphism and nuclear size
 - Loss of cellular maturation and polarity
 - Nuclear hyperchromasia with irregular nuclear contours
 - Increased nuclear-to-cytoplasmic ratio

Progression to Invasive Carcinoma

- Wide variation in the literature relative to the incidence of laryngeal CIS progressing to invasive carcinoma:

- Discrepant statistics ranging from approximately 3% to as high as 90% reflect inconsistencies in the diagnosis of CIS, which can be a notoriously subjective diagnosis.
- Collated incidence of laryngeal CIS progressing to invasive carcinoma is 23% to 27%.
- Latent period of 3 to 5 years from diagnosis of CIS to invasive carcinoma

Differential Diagnosis

- Reactive epithelial changes
- Microinvasive carcinoma

Treatment and Prognosis

- No standard treatment; treatment may include:
 - Vocal cord stripping
 - Laser surgery
 - Cordectomy
 - Radiation
- Diagnosis of carcinoma in situ should prompt ablative therapy followed by surveillance for recurrence or progression:
 - Surgical excision is preferred treatment.
 - Alternative therapies such as radiation may be employed in selected patients when surgical therapy is not the best option.
- Management offers a high cure rate (approximately 75%):
 - Vigilant follow-up including periodic laryngoscopic examinations should be maintained.
- Risk factor modification remains important not only as a primary prevention strategy but to reduce risk of progression to invasive carcinoma.
- Treatment failures result from:
 - Extensive and/or multifocal disease
 - Associated undetected invasive squamous carcinoma
 - Extension of CIS to subjacent seromucous glands harboring residual disease following the mucosal stripping:
 - Particularly true for CIS of the anterior commissure region, where seromucous glands may be located distant from the opening of their ducts and may lie outside area that is stripped
 - For CIS of anterior commissure additional therapy including laser ablation or irradiation may be indicated.

MICROINVASIVE CARCINOMA

(Figs. 16-24 through 16-27)

Definition: Malignant cells that have penetrated the basement membrane and infiltrate into the superficial compartment of the lamina propria.

Fig. 16-24. Microinvasive carcinoma.

Endoscopic appearance of a microinvasive (T1) laryngeal (vocal cord) squamous cell carcinoma.

Synonym: Superficially invasive squamous cell carcinoma

Clinical

- Clinical manifestations are similar to those of carcinoma in situ.
- In the larynx, full cord mobility is present:
 - Any dysfunction in vocal cord mobility (fixation) by definition means muscle invasion, which excludes a diagnosis of microinvasive cancer.
- Biologically malignant lesion capable of metastasizing either via lymphatic or vascular channels

Pathology

Gross

- Similar to carcinoma in situ

Histology

Diagnostic Criteria for Microinvasive Carcinoma

- Definition of features constituting microinvasion varies in literature:
 - Presence of scattered malignant cells within the submucosa just below the basement membrane
 - Presence of malignant cells limited to 2 mm of invasion
 - Presence of malignant cells within 1 to 2 mm of the basement membrane without angioinvasion
 - Presence of tongues or discrete foci of malignant epithelium invading through the basement membrane
 - Invasive carcinoma extending into the stroma no more than 0.5 mm measured from the epithelial basement membrane and without angioinvasion
 - Represents preferred definition
- Regardless of specific definition, diagnosis of microinvasive carcinoma excludes those lesions that are

Fig. 16-25. Invasive squamous cell carcinoma.

A, Nonkeratinizing severe dysplasia (carcinoma in situ) with development of microinvasive carcinoma; note the invasive tumor nests that, while well-rounded, are below the level of submucosal small vascular spaces. **B**, Keratinizing dysplasia with downward extension of the rete ridges and disruption (penetration) of basement membrane; in addition, a separate nest of invasive carcinoma with associated dyskeratosis is present (left of center). **C**, "Drop-off" or "drop-down" carcinoma in which invasive carcinoma originates from the basal zone of the surface epithelium which otherwise shows bland cytomorphology without dysplasia.

restricted to the surface epithelium or carcinoma in situ (CIS) and those carcinomas that are deeply invasive into muscle and cartilage, and extralaryngeal structures (T2 or greater tumors).

- Microinvasive carcinoma can occur in two unrelated phases:
 - Development from (and as a continuum of) carcinoma in situ:
 - Typically occurs in a setting of nonkeratinizing dysplasia with full-thickness intraepithelial dysplasia:
 - Not a common occurrence relative to dysplastic lesions of the larynx (and oral cavity)
 - Invasion from an epithelium demonstrating dysplastic alterations representing severe dysplasia but lacking full-thickness intraepithelial dysplasia:

- Typically occurs in the setting of a keratinizing high-grade dysplasia (i.e., moderate to severe) in which the (micro)invasive carcinoma is seen originating from dysplastic epithelial changes limited to the basal zone epithelium with the remainder of the more superficially located epithelium lacking dysplastic change:
 - Such invasive carcinomas are referred to as "drop off" or "drop down" carcinoma.
 - Reinforces the fact that in the upper aerodigestive tract, particularly in the larynx and oral cavity, "classic" carcinoma in situ is not a prerequisite for the development of a (micro)invasive squamous cell carcinoma
- In invasive carcinoma:
 - Tumor nests have an irregular outline with infiltrative borders.

Fig. 16-26. Keratin granuloma.

Keratin granuloma formation is considered as presumptive evidence of invasive carcinoma. **A**, Granulomatous response including multinucleated giant cells rimming amorphous eosinophilic debris. **B**, Isolated keratinizing neoplastic cells are present in and around the granuloma but may not be as overtly identifiable in other cases. **C**, Cytokeratin immunoreactivity confirms the eosinophilic debris as keratin; note the absence of staining in the multinucleated giant cells (*upper right*), which would be reactive for CD68 (not shown).

Fig. 16-27.

Diagrammatic depiction of superficial extending carcinoma (SEC) compared with carcinoma in situ (CIS), microinvasive carcinoma (MIC), and deeply invasive carcinoma (DIC). (Adapted from Barnes L: *Carcinoma in situ*. In Barnes L, editor: *Surgical pathology of the head and neck*, ed 2, New York, 2001, Marcel Dekker, pp 158-161.)

- Invasive nests are cytologically malignant, but invasive carcinomas may be extremely well-differentiated with minimal if any malignant cytologic features.
- Presence of invasive cancer generally results in a desmoplastic host response that includes edematous change immediately around the tumor nests with granulation tissue and fibrosis:
 - Identifying tumor-related desmoplasia from reactive stromal changes not straightforward:
 - There are no clear-cut criteria other than the presence of bona fide malignant cells (in nests or individual cells) to differentiate between tumor-related desmoplasia and reactive stromal changes to assist in a diagnosis of invasion.
 - In setting of well-differentiated squamous epithelium within the submucosa it can be very difficult if not impossible to determine neoplastic (malignant) epithelium from nonneoplastic squamous epithelium that is reactive and/or represents tangentially sectioned squamous epithelium:
 - No immunostains or molecular markers available to assist in such a differentiation
 - In such a scenario a diagnosis of carcinoma may not be possible and a designation of “well-differentiated squamous epithelial proliferation, not further specified” may be required with recommendation for:
 - Additional deeper biopsies
 - Conservative but complete excision of the lesion
 - Keratin granuloma formation in the submucosa represents supportive evidence of (at least) microinvasive carcinoma:
 - Represents a foreign body reaction to keratin in the submucosa
 - Appears as relatively well-formed granuloma formation, including the presence of histiocytes and multinucleated giant cells
 - Keratin material may or may not be identified by light microscopy.
 - May require cytokeratin immunohistochemical staining (e.g., AE1/AE3, CAM5.2, others) to confirm the presence of keratin-positive material
 - In the absence of cytokeratin-positive material, a diagnosis of keratin granuloma cannot be rendered.
 - Histiocytes and giant cells are CD68 (KP1) positive.

Differential Diagnosis

- Pseudoepitheliomatous hyperplasia
- Superficial extending carcinoma (see [Fig. 16-27](#)):
 - Early invasive carcinoma that does not extend beyond lamina propria
 - In contrast to microinvasive carcinoma, which is predominantly an in situ carcinoma with definite but limited invasion into the lamina propria, superficial extending carcinoma shows extensive invasion into (but not beyond) the lamina propria.
 - By definition there is no invasion into muscle or cartilage.
 - Associated carcinoma in situ is often present.
 - May be multifocal
 - Establishing this diagnosis may be problematic in limited biopsy sampling and may require surgical excision with thorough histologic evaluation.
 - Limited reports to date and the long-term prognosis remains uncertain
 - Presence of nodal metastasis in the setting of superficial extending carcinoma may exclude this entity as an “early” carcinoma.

Treatment and Prognosis

- No standardized approach to treatment:
 - Most authorities advocate conservative management with endoscopic removal of the lesion (mucosal stripping with or without laser ablation) and close clinical follow-up of the patient rather than surgical resection (e.g., some type of laryngectomy) or radiation.
 - Behavior is similar to that of carcinoma in situ, and if presence of a coexisting invasive squamous cell carcinoma can be excluded, then therapy is similar to carcinoma in situ.
- Conservative management supported by:
 - Studies have shown that in cases in which hemilaryngectomy was performed, no residual carcinoma was found in 20% of patients, indicating that the lesion was totally excised in original biopsy.
 - For microinvasive carcinoma of the laryngeal glottis, several studies have shown that the clinical significance is similar to CIS/severe dysplasia and that with appropriate therapy progression of disease from a microinvasive to a more invasive carcinoma does not occur.
 - This finding may be due to earlier clinical manifestations produced by glottic cancers, leading to an earlier diagnosis of cancer before it has invaded into deeper aspects of the larynx.
 - Glottic microinvasive cancers are generally not associated with metastatic disease due to the fact that glottic portion of the larynx has quantitatively less lymph-vascular spaces as compared with the supra- and subglottis.
- In contrast to laryngeal glottis, supraglottic microinvasive carcinomas are associated with metastatic disease in approximately 20% of patients.

Fig. 16-28. Invasive well-differentiated squamous cell carcinoma.

A, Invasion includes cohesive nests and cords.
B, Keratinization and intercellular bridges are readily apparent.

LARYNGEAL INVASIVE SQUAMOUS CELL CARCINOMA

(Figs. 16-28 through 16-30)

General Considerations

- Laryngeal squamous cell carcinoma (SCC) accounts for approximately 0.8% of all cancers, 1.0% of all cancers in men, and approximately 0.3% of all cancers in women.
- Represents greater than 95% of all laryngeal carcinomas
- More common in men than in women; most commonly occurs in the fifth through seventh decades of life:
 - There has been an increase of laryngeal carcinoma in women over the past 20 years, likely linked to increase tobacco use in women over this time period.
 - Less than 1% occur in patients under 30 years of age.
- Rarely occurs in pediatric ages (first and second decades of life):
 - More common in girls than boys
 - Most occur in glottic region
 - Hoarseness most common complaint
 - No known risk factors but possible relationship to HPV and passive smoking exposure
- Cause:
 - Association with tobacco smoking:
 - Tobacco linked to glottic carcinoma:
 - Less than 5% of patients with laryngeal carcinoma are nonsmokers.
 - Alcohol linked to supraglottic carcinoma but less important risk factor as compared with tobacco use

Fig. 16-29. "Drop off" invasive squamous cell carcinoma.

Example of a deeply invasive squamous cell carcinoma in which the carcinoma "drops off" from the basal zone of the surface epithelium, which otherwise shows bland cytomorphology and absence of full-thickness dysplasia.

Fig. 16-30. Extranodal extension.

Laryngeal squamous cell carcinoma metastatic to cervical neck lymph node with extranodal extension, the latter characterized by the presence of carcinoma in perinodal soft tissues (upper left).

- Other potential contributing etiologic factors associated with but not definitively linked as a direct cause of squamous cell carcinoma include:
 - Genetic factors
 - Human papillomavirus infection
 - Dietary deficiencies (vitamin A, vitamin C, iron)
 - Previous irradiation to the neck
 - Environmental/occupational exposure (asbestos, nickel, wood, air pollution, isopropyl alcohol, mustard gas, others)
 - Chronic gastroesophageal reflux disease
- TNM staging of laryngeal carcinoma for all subsites detailed in [Box 16-3](#):
 - TNM staging for hypopharyngeal cancers is detailed in Section 3.
- See below for clinicopathologic features for site-specific laryngeal cancers.

Pathology

Gross

- Variable and includes ulcerated, flat, exophytic, verrucoid, or papillary growths

Histology

- Histologic appearance of invasive SCC may be as variable as gross appearance without specific correlation between gross appearance and the histopathologic findings.
- Invasive SCC includes keratinizing and nonkeratinizing carcinomas varying from well to poorly differentiated.
- Severe dysplasia/carcinoma in situ of the surface epithelium may be a common component found in

association with invasive SCC; this component need not be present.

- For all types of SCC, presence of invasion is diagnostic for malignancy:
 - Invasion can be as single cells or small irregular aggregates or can appear as large cords or cohesive aggregates.
 - Desmoplastic stromal response and foreign body reaction to keratin (keratin granuloma; see [Fig. 16-24](#)) in the stroma assist in identifying invasion.
 - Invasive cancer tends to efface normal histoanatomic architecture:
 - In contrast, lobular growth of seromucous glands is retained in association with sialometaplasia.
 - Invasion may be associated with lymph-vascular invasion, neurotropism, invasion into muscle, bone, and cartilage:
 - Invasion of cartilage often occurs in cartilage that has undergone ossification:
 - Ossification usually occurs in the third decade and not before the third decade of life.
 - Histology is similar to endochondral ossification.
 - Ossification of thyroid cartilage begins at posterior border near the root of the inferior cornu, spreads along inferior border and reaches midline, where there usually is a separate center of ossification.
 - Invasion of the laryngeal cartilage framework usually is in lower third of the thyroid cartilage.
 - Perichondrium appears to resist invasion and remains intact even when the cancer infiltrates and expands the cartilage.
 - Reasons cited for the presence of invasion in ossified cartilage include the absence of perichondrium in this areas.
 - Cartilaginous invasion usually is found in association with transglottic cancers.
 - Once cancer invades beyond a few millimeters or extends into muscle, cartilage, or other soft tissue components outside the anatomic structure from which it originates, then it is a higher clinical stage neoplasm with potential for a more aggressive behavior.
 - Immunohistochemical studies have shown that the presence or absence of basement membrane components around invasive cancer may correlate with pattern of tumor invasion:
 - Pattern of tumor invasion (single cell versus large cords) represents an inherent biologic parameter of tumor aggressiveness.

BOX 16-3 TNM Classification of Laryngeal Carcinoma**Primary Tumor**

- T = extent of the primary tumor
 - Includes the clinical (T) and pathologic (pT) categories
 - T designation varies according to the anatomic site involved
- TX = Primary tumor cannot be assessed.
- T0 = No evidence of primary tumor
- Tis = Carcinoma in situ

Supraglottis

- T1 = Tumor limited to one subsite with normal vocal cord mobility
- T2 = Tumor invades mucosa of more than one adjacent subsite of supraglottis or glottis or region outside the supraglottis (e.g., mucosa of base of tongue, vallecula, medial wall of piriform sinus) without fixation of the larynx
- T3 = Tumor limited to the larynx with vocal cord fixation and/or invades any of the following: postcricoid area, pre-epiglottic tissues, paraglottic space and/or minor thyroid cartilage erosion (e.g., inner cortex)
- T4a = Moderately advanced local disease
 - Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of the neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus)
- T4b = Very advanced local disease
 - Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures.

Glottis

- T1 = Tumor limited to the vocal cord(s) (may involve anterior and posterior commissures) with normal cord mobility:
 - T1a = tumor limited to one vocal cord
 - T1b = tumor involves both vocal cords
- T2 = Tumor extends to the supraglottis and/or subglottis and/or with impaired vocal cord mobility
- T3 = Tumor limited to the larynx with vocal cord fixation and/or invades paraglottic space and/or minor thyroid cartilage erosion (e.g., inner cortex)
- T4a = Moderately advanced local disease
 - Tumor invades through the outer cortex of thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of the neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus)
- T4b = Very advanced local disease
 - Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

Subglottis

- T1 = Tumor limited to the subglottis
- T2 = Tumor extends to the vocal cord(s) with normal or impaired mobility
- T3 = Tumor limited to the larynx with vocal cord fixation

- T4a = Moderately advanced local disease
 - Tumor invades cricoid or thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of the neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus)
- T4b = Very advanced local disease
 - Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

Regional Lymph Nodes (N)

- N = Absence/presence and extent of regional lymph node metastasis; includes the clinical (N) and pathologic (pN) categories
- NX = Regional lymph nodes cannot be assessed.
- N0 = No regional lymph node metastasis
- N1 = Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
- N2 = Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension, or multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
 - N2a = Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension
 - N2b = Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
 - N2c = Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
 - N3 = Metastasis in a lymph node, more than 6 cm in greatest dimension
- Metastases at Level VII are considered regional lymph node metastasis

Distant Metastasis (M)

- M = Absence or presence of distant metastasis; includes both the clinical (M) and pathologic (pM) categories
- M0 = No distant metastasis
- M1 = Distant metastasis present

Clinical Stage

- Stage 0 = TisN0M0
- Stage I = T1N0M0
- Stage II = T2N0M0
- Stage III = T3N0M0
 - T1N1M0
 - T2N1M0
 - T3N1M0
- Stage IVA = T4aN0M0
 - T4aN1M0
 - T1N2M0
 - T2N2M0
 - T3N2M0
 - T4aN2M0
- Stage IVB = T4b Any N M0
 - Any T N3M0
- Stage IVC = Any T Any N M1

- Sampling represents a major issue in the evaluation of SCC:
 - In absence of adequate representative tissue including epithelial-to-stromal interface, one should be circumspect relative to rendering a diagnosis of invasive SCC.
 - Diagnostic pitfalls in diagnosis of laryngeal SCC include pseudoepitheliomatous hyperplasia, necrotizing sialometaplasia, and radiation atypia.
- Factors affecting prognosis:
 - Tumor location:

- Transglottic tumors have higher incidence of lymph node metastasis compared with supraglottic and subglottic carcinomas.
- Tumor size:
 - Larger tumors have greater chance of metastasis.
- Tumor histology:
 - Poorer differentiation (grade) more likely to disseminate
- Cervical lymph node metastasis:
 - Metastatic tumor to cervical lymph nodes decreases survival by 50%.
 - Tumor extending beyond the confines of the lymph node into perinodal soft tissues (extranodal extension; see Fig. 16-30) represents an important finding relating to:
 - Recurrent disease in neck
 - Increased risk for distant metastasis
 - Presence or absence of extranodal extension should be specifically commented on in pathology report.
- Multiple malignancies:
 - Up to 12% of patients with laryngeal carcinoma develop a secondary primary malignant tumor either in lung, another upper aerodigestive tract site, or, less commonly distant unrelated site.
- Surgical resection margins:
 - For laryngeal carcinomas, a margin of resection of 2 mm is considered adequate:
 - In larynx margins of 2 mm or greater have been shown to have a similar behavior to margins with greater clearance (e.g., 5 mm).
 - Other studies have reported that in laryngeal squamous cell carcinomas:
 - 18% develop local recurrence with positive surgical margins
 - 6% develop local recurrence with negative margins
 - As compared with extralaryngeal mucosal sites, patients with primary laryngeal squamous cell carcinoma with positive surgical margins have a significantly lower incidence of local recurrence:
 - Larynx perhaps is an outlier in regard to positive margins and local recurrence.
 - Above findings suggest that margin status and local recurrence are site dependent and assist in explaining why surgeons are more apt to accept nearer margins for laryngeal carcinoma (free margins up to 2 mm) but require wider margins (5 to 10 mm) for carcinomas of extralaryngeal mucosal sites.
 - Factors that may contribute to the lower incidence of local recurrences in laryngeal

squamous cell carcinoma with positive margins supporting organ sparing (conservative) laryngectomy may include:

- These patients have early-stage carcinoma associated with a more favorable prognosis.
- Submucosa of the glottic region has (quantitatively) fewer lymph-vascular spaces, thereby decreasing the incidence of spread and lowering the incidence of locoregional failure.

Supraglottic Squamous Cell Carcinoma (Fig. 16-31)

Definition: Squamous cell carcinoma that involves structures of supraglottic larynx, including the epiglottis (laryngeal and lingual surfaces), aryepiglottic folds, arytenoids, false vocal cords, and ventricles.

Clinical

- Accounts for 30% to 35% of all laryngeal carcinomas
- In descending order supraglottic carcinomas involve epiglottis (45% to 55%) > false vocal cords (12% to 33%) > aryepiglottic folds (8% to 21%) > ventricles (4% to 7%) and arytenoids (5% to 6%):
 - In combination with other sites epiglottis is involved in 70% to 90% of cases.
 - Marginal or epilaryngeal carcinomas represent carcinomas involving the suprahoid epiglottis and aryepiglottic folds and account for approximately 20% of cases.
- Symptoms include:
 - Dysphagia, changes in quality of voice, foreign body sensation in the throat, neck mass, hemoptysis, odynophagia, and dyspnea
 - Marginal (epilaryngeal) carcinomas tend to remain quiescent for longer periods and present with more advanced disease.

Pathology

Gross

- Vary in size and appearance:
 - Tend to be large
 - Ulcerated, flat, exophytic, or rarely papillary

Histology

- Tend to be moderately to poorly differentiated carcinomas
- An in situ component is common and may be extensive.
- Invasive pattern can be pushing or infiltrative.
- Mitoses and necrosis can be seen and their presence relates to the grade of the tumor (tend to be more common with poorer differentiated tumors).

**Fig. 16-31.**

A, B, Supraglottic laryngectomy specimens showing supraglottic-based (squamous cell) carcinoma.

Spread

- Tendency for supraglottic carcinomas to spread:
 - Upward toward the free margins of the epiglottis and aryepiglottic folds
 - Into piriform sinus

- Into vallecula (i.e., base of tongue)
- High incidence of invasion of the preepiglottic space:
 - Involvement of the preepiglottic space is associated with an increased incidence of nodal metastasis.
- Uncommon to spread posteriorly to arytenoids or to glottis or thyroid cartilage
- Marginal carcinomas tend to spread to:
 - Base of tongue
 - Less common to spread to the pre-epiglottic space

Treatment and Prognosis

- Treatment depends on stage:
 - Early stage lesions (T1N0 and T2N0):
 - Radiation therapy or supraglottic laryngectomy with or without adjuvant radiotherapy
 - Advanced-stage lesions (T3 and T4):
 - Combined modalities often including total laryngectomy and adjuvant radiotherapy:
- Decision to use radiation therapy or partial laryngeal therapy depends on several factors, including:
 - Anatomic extent of the tumor
 - Medical condition of the patient
 - Status of the surgical margins
 - Presence or absence of nodal metastasis with or without extracapsular spread
 - Philosophy of the treating physician
 - Inclination of the patient and family
- Potential for nodal metastasis even in early-stage lesions is substantial, and neck dissection is often performed in conjunction with laryngeal surgery:
 - Majority of supraglottic carcinomas are located in epiglottis and many of these tumors are midline, putting the patient at risk for contralateral neck metastases, thereby necessitating bilateral neck dissection.
 - Site of treatment failure in supraglottic carcinoma is neck, requiring neck management for supraglottic carcinomas.
 - For the N0 neck, selective neck dissection or elective radiation is indicated.
 - For clinically positive neck disease, neck dissection, therapeutic irradiation, or combination of both indicated
 - Supraglottic larynx is rich in lymphatic spaces, increasing the likelihood of cervical lymph node metastasis even in early-stage disease.
 - Increased rates of cervical lymph node metastasis correlated to:
 - Tumor size: larger tumors (>4 cm) have higher rate of metastasis
 - Location:
 - Tumors arising from marginal supraglottis have higher rate of metastasis
 - Anterior tumors or tumors that cross the midline may produce bilateral metastases

- Supraglottic lymphatic drainage is to upper and middle jugular chains.
- Distant metastasis (i.e., below the clavicle) from supraglottic cancers is uncommon (5% to 15%) and when it occurs more commonly involves the lung and mediastinal lymph nodes
- Overall 5-year survival rate for all stages of supraglottic carcinomas is 65% to 75%:
 - Prognosis depends on:
 - Extent and location of the primary lesion
 - Presence of cervical lymph node metastasis:
 - Appears to represent most important determinant of survival
 - Influenced by location of primary tumor (see above)
 - Occurs in 30% to 40% of cases
 - Most commonly involves upper and midjugular lymph nodes
 - Uncontrolled neck metastasis is a source of therapeutic failure.
 - Nature of the primary therapy

Glottic Squamous Cell Carcinoma

(Fig. 16-32)

Definition: Squamous cell carcinoma that involves structures of glottis, including the true vocal cords, and anterior and posterior commissures.

Clinical

- Represents from 60% to 65% of all laryngeal squamous cell carcinomas
- Majority arise from anterior portion of true vocal cord:
 - Involvement of anterior commissure alone is uncommon (less than 10% of cases)
 - Secondary involvement is more common, seen in up to 46% of cases.
 - Posterior portion of true vocal cord is uncommon site for carcinoma to develop.
 - Equally distributed between right and left true cord
- Most common presenting symptom is hoarseness.
- As a result of interference with vocal cord mobility symptoms develop early in the course of disease.
- Many glottic carcinomas are small, limited in size, tend to be localized and are amenable to conservative therapy.

Pathology

Gross

- Early lesions:
 - Irregular area of mucosal thickening of varying size
- Advanced lesions:
 - Exophytic, fungating, endophytic, or ulcerated mass, which can attain a large size

Fig. 16-32.

Laryngectomy specimen showing a glottic-based (squamous cell) carcinoma.

Histology

- Most often are well-differentiated to moderately differentiated squamous cell carcinomas
- High-grade intraepithelial dysplasia/CIS seen adjacent to invasive carcinoma
- Invasive pattern is predominantly infiltrative but can be pushing.

Spread

- Spread of glottic carcinomas include:
 - Across the anterior commissure to involve the opposite vocal cord
 - Anteriorly through the Broyle's ligament (anterior commissure tendon) with deep invasion and penetration of the thyroid cartilage in the midline with invasion of the soft tissues of the neck
 - Posteriorly to involve arytenoids
 - Extension to supraglottis with involvement of the ventricle, false vocal cords, and epiglottis:
 - Occurs in approximately 20% to 25% of cases

- Extension to subglottis:
 - Occurs in approximately 20% to 25% of cases
 - Greater access to lymphatic channels with potential for spread to paratracheal and mediastinal lymph nodes
 - Potential to invade cricothyroid membrane growing into soft tissues of the neck
 - Do not invade thyroid cartilage until more than 1 cm into subglottis
- Extension into Reinke space along the vocal cord ligament with infiltration into the vocalis muscle:
 - This pattern of invasion defines vocal cord fixation.
 - In presence of fixed cord incidence of nodal metastasis is approximately 25%.
 - If cord is not fixed, then invasion is superficial to conus elasticus.
 - Absent cord fixation incidence of nodal metastasis is less than 2%.
- Incidence of nodal metastasis in T1 lesions ranges from 0 to 6%.
- Incidence of nodal metastasis in T2 lesions ranges from 4% to 11%.
- Majority of cervical lymph node metastasis occurring in glottic carcinomas is seen in T3 and T4 lesions:
 - Incidence of nodal metastasis in T3 lesions ranges from 14% to 22%.
 - Incidence of nodal metastasis in T4 lesions ranges from 25% to 41%.
- Overall 5-year survival rates include:
 - T1: 82% to 96%
 - T2: 51% to 85%
 - T3: 48% to 59%
 - T4: 0 to 30%
- Risk factors associated with incidence of locoregional failure include:
 - Prior tracheotomy
 - Poor histologic differentiation
 - Subglottic extension >1 cm
 - Histologically positive lymph nodes
- Risk of distant metastases increased in association with presence of metastatic carcinoma to a lymph node with extranodal invasion into perinodal soft tissue (extranodal extension)

Treatment and Prognosis

- Treatment depends on staging:
 - For early glottic cancers (T1 and T2) excellent control can be achieved by radiation or partial laryngectomy or even endoscopic resection in some lesions.
 - Advantages of radiation include:
 - Better voice control than that achieved by hemilaryngectomy
 - Hemilaryngectomy (i.e., vertical hemilaryngectomy) can be used successfully for salvage in those patients in whom radiation has failed.
 - For advanced glottic cancers (T3 and T4) total laryngectomy with or without radiation therapy:
 - Not all advanced glottic cancers require total laryngectomy.
 - Certain T3 glottic cancers, including those with mobile arytenoids and less than 7 mm of subglottic extension, are potential candidates for subtotal laryngectomy.
- Neck dissection (radical neck dissection or modified radical neck dissection):
 - Performed in patients with clinically N+ neck disease
 - For advanced glottic carcinomas rates of occult metastasis in clinically N0 neck approach 20% and are higher for those carcinomas that cross the midline, so these patients may be considered for elective neck dissection for staging purposes when surgery is performed for primary disease.
 - Glottic lymphatic drainage is to upper and lower jugular chains.
- Glottic region has sparse lymphatic drainage; as such the overall incidence of lymph node metastasis is low:

Subglottic Squamous Cell Carcinoma (Fig. 16-33)

Definition: Squamous cell carcinoma that involves subglottis, which begins 1 cm below apex of ventricle to its inferior border represented by rim of cricoid cartilage.

Clinical

- Considered uncommon, accounting for less than 5% of all laryngeal carcinomas
- Tend to remain clinically quiescent, presenting with advanced disease
- Most common presenting symptoms relate to airway obstruction (dyspnea, stridor) and to vocal cord fixation (voice changes):
 - May necessitate emergency tracheotomy to maintain airway

Pathology

Gross

- Large exophytic, fungating, ulcerating, or endophytic mass

Histology

- Tend to be moderately to poorly differentiated squamous cell carcinoma
- Invasive pattern is predominantly infiltrative.

Fig. 16-33.

Laryngectomy specimen showing a subglottic-based (squamous cell) carcinoma.

Spread

- Tendency to spread circumferentially and anteriorly through the cricothyroid membrane with involvement of thyroid gland and paratracheal and prelaryngeal (Delphian) lymph nodes
- May spread:
 - Posteriorly below the thyroid cartilage with involvement of the cervical esophagus
 - Inferiorly with involvement of the trachea
 - Medially into the cricoarytenoid joint with involvement of the hypopharynx
 - Into the thyroarytenoid muscle to produce vocal cord fixation
 - Superiorly to involve the glottic and supraglottic regions
- Subglottic region of larynx has lymphatic drainage to:
 - Upper and lower jugular lymph node chains
 - Anteriorly to prelaryngeal (Delphian) lymph node, which in turn drains to the pretracheal and supraclavicular lymph nodes
- Posterolateral to the paratracheal lymph nodes, which are continuous with lymph nodes in the superior mediastinum

Treatment and Prognosis

- Treatment is dependent on staging:
 - For early-stage subglottic cancers (T1 and T2):
 - Radiotherapy alone or conservative surgery
 - For advanced-stage subglottic cancers (T3 and T4):
 - Radical surgical extirpation through wide field laryngectomy
 - In general, subglottic tumors present with advanced disease and because of proximity to cricothyroid space and the cricoid cartilage; surgical treatment usually necessitates a total laryngectomy.
 - Due to involvement of the thyroid gland in approximately 10% to 20% of cases, recommended that one or both thyroid lobes be removed
- Radical neck dissection is advocated in advanced subglottic carcinoma:
 - Approximately 15% to 25% of patients have cervical lymph node metastases but paratracheal lymph nodes that are clinically negative (N0) harbor metastatic tumor from subglottic primary carcinoma in up to 50% of cases, leading to recommendation of clearing the paratracheal as well as superior mediastinal lymph nodes.
- Overall 5-year survival rate is approximately 40%:
 - Death due to subglottic carcinoma often due to local or stomal recurrence:
 - Refers to diffuse infiltration of carcinoma at junction of amputated trachea and skin
 - Dreaded complication of total laryngectomy
 - Occurs in approximately 2% to 15% of patients who have had total laryngectomies
 - Most often occurs within 1 to 2 years after total laryngectomy
 - 70% of patients with stomal recurrence die within the first year after laryngectomy and 98% within 2 years.
 - Inadequate tumor resection at the inferior margin contributes to early stomal recurrence.
- Distant metastases occur in 15% to 20%:
 - Most often to lungs and bones

Transglottic Squamous Cell Carcinoma (Fig. 16-34)

Definition: Transglottic carcinoma represents a carcinoma that crosses ventricles in a vertical direction to involve supraglottis and glottis (and often subglottis):

- Most likely are glottic cancer with supraglottic extension

Fig. 16-34. Transglottic carcinoma.

A, Transglottic carcinoma characterized by carcinoma that crossed the ventricles in a vertical direction with involvement of the glottic and supraglottic larynx. **B,** Bilateral vocal cord paralysis in a patient with a transglottic carcinoma. **C,** Patients with transglottic carcinoma have a high incidence of nodal metastasis as seen in this patient with a right lateral neck mass histologically composed of a keratinizing squamous cell carcinoma.

Clinicopathologic Features

- Usually but not always represent advanced-stage tumors
- Majority are moderately differentiated with infiltrating margins.
- High incidence of nodal metastases and extralaryngeal spread:
 - Extralaryngeal spread present in approximately one third of patients
 - Spread to paraglottic space
 - Submucosal spread to piriform sinus
 - Extralaryngeal escape by growing through the cricothyroid or thyrohyoid membranes
- Should be suspected in patients with referred otalgia
- 26% with nodal metastasis at presentation and additional 19% subsequently develop positive lymph nodes during course of disease
- High incidence of vocal cord paralysis
- May be understaged as a result of undetectable cartilaginous invasion
- Treatment generally requires radical surgery and radiotherapy.
- In limited patients conservation techniques may be used.
- Overall 5-year survival is approximately 50%.

Tracheal Squamous Cell Carcinoma

Clinical

- Most common malignant neoplasm of the trachea
- More common in men than in women; most common in the fifth to seventh decades of life
- Clinical presentation includes stridor, cough, hemoptysis, hoarseness, weight loss; superior vena cava syndrome may occur in minority of cases:
 - Delay in diagnosis is common as symptoms may be attributed to asthma.
- Tracheal carcinoma at the level of the thyroid can be misinterpreted as invasive thyroid cancer.
- In order of frequency tracheal carcinomas occur:
 - Lower third (45%) > upper third (32%) > middle third (15%) > multiple sites (8%)
- Cause:
 - Most patients reported to be heavy tobacco smokers

Pathology

Gross

- Polypoid mass protruding into the tracheal lumen:
 - Most tend to be large, measuring 4 cm in greatest dimension.
- Uncommonly grows circumferentially or with an annular appearance

Histology

- Variable architectural features including exophytic and papillary
- Variable morphologic findings ranging from well to poorly differentiated

Spread

- Invasion through tracheal wall is common.
- Lymph node metastasis is common and includes spread to paratracheal, deep cervical, mediastinal, and peribronchial lymph nodes.

Treatment and Prognosis

- Surgical resection and primary reconstruction is best curative treatment modality available at present:
 - Many tracheal carcinomas are too large or extensive at presentation for surgical cure.
- In patients with advanced disease (i.e., inoperable tumors), radiotherapy can represent a management option:
 - Variable success in controlling disease
- Approximately 35% have nodal metastasis at presentation.
- Distant metastases commonly occur:
 - Primarily to lungs, liver, and bones
- Clinical course is rapid and prognosis is poor:
 - 5-year survival rates 5% to 15%
 - 10-year survival rates 6% to 7%

BOX 16-4 Variants of Squamous Cell Carcinoma

- Papillary squamous cell carcinoma
- Verrucous carcinoma
- Spindle cell squamous carcinoma
- Basaloid squamous cell carcinoma
- Adenosquamous carcinoma
- Lymphoepithelial-like carcinoma
- Giant cell carcinoma
- Others

- There is no current TNM classification for tracheal carcinomas.

VARIANTS OF SQUAMOUS CELL CARCINOMA (Box 16-4 and Table 16-3)

Papillary (Exophytic) Squamous Cell Carcinoma (PSCC)

(Figs. 16-35 through 16-37)

Definition: Invasive squamous cell carcinoma with a predominant papillary and/or exophytic component.

Clinical

- Uncommon but distinct subtype of head and neck SCC
- Demographics are similar to those of conventional SCC with the tendency to affect men more than women and occurring in adults with a mean age in the seventh decade of life.
- Predilect to the larynx, oral cavity, oropharynx, hypopharynx, and sinonasal tract:
 - Larynx is most common site of occurrence.
 - Within the larynx most of these carcinomas are located in the supraglottis followed by the glottis and rarely in the subglottis.
 - Less commonly, may occur in other mucosal sites of the upper aerodigestive tract including (but not limited to):
 - Oropharynx (tonsil and base of tongue), oral cavity, sinonasal tract, nasopharynx
- Symptoms vary according to the site of involvement:
 - Laryngeal involvement includes hoarseness and airway obstruction; less often, dysphagia and hemoptysis may occur.
- Development:
 - Majority arise de novo unassociated with pre- or coexisting papilloma
 - Minority develop in association
- Cause:
 - Etiologically associated with human papillomavirus (HPV) but histology and subsite localization may corroborate whether HPV may be involved:

TABLE 16-3 Clinicopathologic Features of Select Squamous Cell Carcinoma Variants

	PSCC	VC	SCSC	BSCC
Age/Gender	7th decade; M > F	6th-7th decades; M > F	6th-8th decades; M > F	6th-7th decades; M > F
Site*	Larynx > oropharynx, oral cavity, sinonasal tract nasopharynx	Oral cavity > larynx (glottis)	Larynx: true vocal cord > false vocal cord, supraglottis	Hypopharynx (piriform sinus), larynx (supraglottis), oropharynx (tonsil, base of tongue)
Symptoms	Hoarseness and airway obstruction	Oral: mass with or without pain Larynx: hoarseness	Hoarseness, airway obstruction, dysphagia	Hoarseness, dysphagia, pain, neck mass
RF	Tobacco and alcohol	Tobacco (chewing, smoking)	No known risk factors	Tobacco and alcohol
HPV-associated (transcriptionally active)	Transcriptionally active high-risk HPV may be identified	Not implicated	Transcriptionally active high-risk HPV may be identified; often site specific [†]	Transcriptionally active high-risk HPV may be identified; often site specific [†]
Histology	Filiform to papillary to broad-based bulbous to exophytic growth with fibrovascular cores; squamous epithelium is cytologically malignant; surface keratinization is generally limited and often absent; considered as being invasive even in the absence of definitive stromal invasion; usually arise de novo but may be associated with precursor papilloma or occurrence at site of prior papilloma	Epithelial proliferation with uniform squamous cells without dysplastic features or mitoses; marked surface keratinization ("church-spire" keratosis); broad or bulbous rete pegs with a pushing, not infiltrative, margin	Malignant undifferentiated spindle cell and pleomorphic cellular proliferation and the presence of a conventional squamous cell component (carcinoma in situ and/ or invasive SCC); may be entirely composed of malignant undifferentiated spindle cells (cellular or hypocellular collagenized) without differentiated epithelial component	Invasive neoplasm composed predominantly of pleomorphic basaloid cells with associated minor squamous cell component (epithelial dysplasia, abrupt keratinization, carcinoma in situ, invasive carcinoma); variety of growth patterns, including solid, lobular, cribriform; cords, trabeculae and gland-like or cystic growth; increased mitotic activity, comedonecrosis in center of neoplastic lobules; peripheral nuclear palisading and basement membrane- like material may be seen
IHC	Positive for cytokeratins (IHC typically not required for diagnosis); p16 typically negative	Positive for cytokeratins (IHC typically not required for diagnosis); p16 typically negative	Positive for cytokeratins in majority of cases (approximately 60%), but may be negative in approximately 40% of cases; variable reactivity for p63; may be positive for vimentin, desmin, actins; p16 typically negative but may be positive [†]	Consistently positive for cytokeratins; neuroendocrine markers are usually negative but occasional cases may be positive; variable expression for vimentin, NSE, S100 protein, and actins; site specific tumors may be p16+ [†]
Treatment	Surgery	Surgery	Surgery with or without adjunctive radiotherapy	Surgery, ND, radiation, and chemotherapy
Spread	Regional lymph nodes; distant metastasis is rare (lung)	Locally invasive; not metastatic	Metastasizes to regional lymph nodes and lung	Early dissemination to regional and distant lymph nodes, lung, bone, skin, brain

Continued

TABLE 16-3 Clinicopathologic Features of Select Squamous Cell Carcinoma Variants—cont'd

	PSCC	VC	SCSC	BSCC
Prognosis	Similar to conventional SCC of similar stage although may have an overall more favorable prognosis than comparable conventional SCC; HPV-related PSCCs not associated with statistically significant improved patient outcomes, although the HPV-positive tumors tend to have better survival compared with the HPV-negative tumors	Excellent	Dependent on stage but overall prognosis is poor Although number of HPV-positive cases are too small for any definitive conclusions, positive viral status does not appear to confer any prognostic benefit	For non-HPV-associated: poor, often resulting in death within a year from diagnosis For HPV-associated BSCC: share better outcomes similar to oropharyngeal nonkeratinizing (HPV-associated) carcinomas

BSCC, Basaloid squamous cell carcinoma; HPV, human papillomavirus; IHC, immunohistochemistry; ND, neck dissection; PSCC, papillary squamous cell carcinoma; RF, potential risk factors; SCSC, spindle cell squamous carcinoma; VC, verrucous carcinoma.

*Most common sites in the head and neck.

[†]Oropharyngeal BSCCs and SCSCs may harbor transcriptionally active HPV.

- Oropharyngeal PSCCs tend to be nonkeratinizing and associated with high-risk HPV.
- Laryngeal and oral PSCCs tend to be keratinizing and not associated with HPV.
- Smoking and alcohol linked to the development of PSCC

Pathology

Gross

- Most often seen as a solitary lesion with a polypoid, exophytic, or papillary growth
- Tumor size may range from 2 mm up to 4 cm.

Histology

- Filiform growth with finger-like projections and identifiable fibrovascular cores or a broad-based bulbous to exophytic growth with rounded projections resembling a cauliflower-like growth pattern in which fibrovascular cores can be seen but tend to be limited to absent.
- Squamous epithelium is cytologically malignant:
 - Malignant epithelium identifies these tumors as carcinomas as opposed to papillomas.
- Surface keratinization is generally limited and often absent.
- Two morphologic types may be identified:
 - Keratinizing type:
 - Epithelial cells show maturation with minimal surface parakeratin.
 - Tend to predilect to larynx, oral cavity
 - Tend to be p16 negative and p53 positive:
 - May be p16 positive

- Tend to lack transcriptionally active virus:
 - May be shown to harbor transcriptionally active virus
 - Oral cavity and to a lesser extent larynx more likely to be associated with transcriptionally active HPV than conventional SCC.
- Nonkeratinizing type:
 - Papillae completely covered by immature basaloid cells
 - Tend to predilect to oropharynx
 - Tend to be p16 positive and p53 negative
 - Tend to harbor transcriptionally active virus
- May be entirely in situ (irrespective of size) or show only superficial invasion:
 - Definitive invasion may be difficult to demonstrate in biopsy specimens.
 - Multiple biopsies may be required to establish the diagnosis.
 - Some authorities believe that, despite the presence of carcinomatous epithelium suggesting an in situ process rather than invasive carcinoma, the extent of growth with the formation of a clinically appreciable exophytic mass goes beyond the general concept of an in situ carcinoma and that these tumors should be considered as being at least superficially invasive even in the absence of definitive stromal invasion.
- Usually arise de novo without identification of coexisting benign lesion such as a papilloma although association with precursor papilloma or occurrence

Fig. 16-35. Resected PSCC.

Laryngectomy specimen showing papillary squamous cell carcinoma appearing as a solitary papillary/exophytic lesion in the supraglottic larynx.

in patients with previous history of a papilloma at the site of the papillary SCC has been reported

- Immunohistochemistry and molecular genetics:
 - Transcriptionally active high-risk HPV may be identified:
 - Indirectly by p16 overexpression
 - Directly by mRNA in situ hybridization (ISH) for E6/E7 proteins
 - Tend to be located in oropharynx with non-keratinizing morphology
 - Oral cavity and less often laryngeal PSCC may be shown to harbor transcriptionally active HPV by p16 staining and E6/E7 mRNA ISH
 - p53 immunoreactivity reported:
 - Tend to occur in keratinizing type
 - Tend to be absent in nonkeratinizing type

Differential Diagnosis

See Table 16-3.

- Papilloma/papillomatosis:
 - Papillomas are distinguished by their bland epithelial proliferation.
 - Cytologic abnormalities may be seen in papillomas, but they tend to be focal when present but do not approach the level of dysplasia seen in papillary SCC.
- Conventional squamous cell carcinoma
- Verrucous carcinoma:
 - Characterized by a verrucous growth pattern with marked keratosis in layers or tiers, absent nuclear atypia, absent mitotic activity beyond the basal layer, and a pushing rather than infiltrative pattern of invasion:
 - Such features contrast with those seen in PSCC.

Treatment and Prognosis

- Surgery is preferred treatment.
- Adjunctive therapy (i.e., radiation) may be used.
- Majority of papillary SCCs are low clinical stage (T2)
- Overall behavior similar to conventional SCC of similar stage, although a better overall prognosis reported for PSCC than for conventional SCC when matched for T stage.
 - 2- and 5-year disease-free survival rates reported to be 68% and 46%, respectively
 - Overall survival rate reported to be 90% and 72% at 2 and 5 years, respectively
- Recurrence and metastasis (locoregional and distant) may occur:
 - Distant metastases are rare and may include the lung.
- HPV-related PSCCs:
 - Not associated with statistically significant improved patient outcomes, although the HPV-positive tumors tend to have better survival compared with the HPV-negative tumors
 - Even though PSCCs in larynx and oral cavity harbor transcriptionally active HPV, it has been not shown that they are biologically different from HPV-negative ones or that they should be treated differently
 - Based on current state of knowledge, HPV testing in routine practice advocated only for oropharyngeal PSCC with no known utility for HPV testing in PSCCs of larynx and oral cavity
- p53 staining reported to be associated with poor survival

Fig. 16-36. Papillary squamous cell carcinoma.

Papillary/exophytic squamous cell carcinoma showing (A and B) papillary or filiform growth, (C and D) broad-based bulbous to rounded exophytic growth. Note the absence of surface keratosis.

Verrucous Carcinoma (VC)

(Figs. 16-38 through 16-40)

Definition: Highly differentiated variant of squamous cell carcinoma with locally destructive but not metastatic capabilities characterized by exophytic and/or warty appearance, absence of epithelial dysplasia, and presence of pushing margins.

Synonym: Ackerman tumor

Clinical

- Affects men more than women; generally occurs in the sixth and seventh decades of life
- Can occur anywhere in the upper aerodigestive tract, but most common sites of occurrence include:
 - Oral cavity:
 - Represents the most common site of occurrence in the head and neck, accounting for approximately 75% of all cases

Fig. 16-37. PSCC.

The epithelium in papillary squamous cell carcinoma is cytologically malignant, which differentiates it from a papilloma; surface keratosis is absent.

- Most commonly arise on the buccal mucosa and gingiva
- Larynx:
 - Represents the second most frequent site of occurrence
 - Accounts for 15% to 35% of all VCs
 - Represents from 1% to 4% of all laryngeal carcinomas
 - Most common site of occurrence in the larynx is the glottic area (anterior true vocal cord); less common sites of occurrence include the supraglottis, hypopharynx and subglottis, and trachea.
- Nasal fossa
- Sinonasal tract and nasopharynx
- Middle ear (rare)
- Symptoms vary according to site:
 - Larynx: hoarseness is most common complaint, less frequent symptoms include airway obstruction, hemoptysis, dysphagia
 - Oral cavity: mass with or without pain
 - Sinonasal tract: airway obstruction
 - Nasopharynx: dysphagia

Fig. 16-38. Verrucous carcinoma.

Laryngeal verrucous carcinoma appearing as a large, tan-white, and warty to fungating mass.

- Cause of VC remains speculative and includes:
 - Tobacco smoking or chewing
 - Most recent data from the literature do not support etiologic link to HPV (high risk or low risk).
 - Active role of HPV is more likely as a promoter in the multistep process of carcinogenesis in squamous cells of the upper aerodigestive tract.
 - Two viral oncoproteins of high-risk HPVs, E6 and E7, promote tumor progression by inactivating the p53 and retinoblastoma tumor suppressor gene products, respectively, thereby disrupting cell-cycle regulatory pathways in the genetic progression to head and neck SCC.

Pathology

Gross

- Tan or white, warty, fungating or exophytic, firm to hard mass of varying size measuring up to 9 to 10 cm in diameter
- In general, the tumors are attached by a broad base.

Histology

- Histologic appearance is that of a benign-appearing squamous cell proliferation, requiring the following characteristics for diagnosis:
 - Marked surface keratinization (“church-spire” keratosis):
 - Filiform projections
 - Commonly in form of parakeratin
 - Orthokeratin with sparse keratohyaline granules may be present.
 - Uniform cells without dysplastic features or mitoses:
 - Cells arranged in orderly maturation pattern toward (markedly keratotic) surface
 - Mitotic figures can be seen along basal zone but should not be present in more superficial aspects of the epithelium.
- Advancing front of tumor characterized by broad or bulbous rete ridges with a pushing but not infiltrative margin with smooth stromal interface
 - Extends below level of identifiable intact subjacent normal epithelium
- Chronic inflammatory cell infiltrate composed of lymphocytes, plasma cells, and histiocytes may be prominent along the advancing front of the tumor.
- Immunohistochemistry and molecular genetics:
 - May be p16 (false) positive showing patchy staining lacking diffuse (greater than 75%) nuclear and cytoplasmic staining associated with true positive reactivity
 - Lack evidence of transcriptionally active high-risk HPV by DNA polymerase chain reaction (PCR) and E6/E7 mRNA reverse transcription PCR
 - p53 overexpression may be found.

Fig. 16-39. Histology of verrucous carcinoma.

The histologic features of verrucous carcinoma include (**A, B**) marked surface keratinization (“church-spire” keratosis), bulbous rete pegs “pushing” into the underlying stroma;

Fig. 16-39, cont'd

(C) rounded rete pegs with absence of cytologic atypia; (D) mitotic figures can be seen but are limited to the basal zone area. Note the rounded nests with smooth stromal interface.

Fig. 16-40. Squamous cell carcinoma with verrucoid features.

A, The histologic features of laryngeal squamous cell carcinoma with verrucoid features at low magnification may suggest a possible diagnosis of verrucous carcinoma. **B**, At higher magnification despite cytologically bland-appearing elongated/angulated rete ridges (*left*) areas of marked dysplasia are present, conferring a diagnosis of a conventional squamous cell carcinoma differentiating it from verrucous carcinoma. The overall changes were not those of a hybrid carcinoma (i.e., admixture of verrucous carcinoma and conventional squamous cell carcinoma). Hybrid carcinomas may occur in the larynx but more often occur in oral cavity lesions.

Hybrid Carcinoma

- Tumor showing mixed histology, including foci of VC and foci of conventional squamous cell carcinoma:
 - Biologic risk is that of conventional SCC including potential for metastatic tumor.
 - May occur in larynx but more commonly seen in oral cavity lesions
 - Careful sampling and evaluation of the depth of the lesion are important to exclude a possible diagnosis of hybrid carcinoma.
 - Some authorities suggest that the SCC component be invasive >2 mm beyond verrucous component.

Biopsy Diagnosis of Verrucous Carcinoma

- Pathologic diagnosis of VC may be extremely difficult, requiring multiple biopsies over several years prior to identification of diagnostic features supporting appropriate interpretation:
 - Clinician and pathologists should be aware of this fact.
 - Adequate biopsy material is critical to interpretation and should include adequate epithelial-stromal interface.
 - Pathologist should not overinterpret a verrucoid lesion as a carcinoma without adequate tissue sampling including the presence of ample subjacent stroma.
 - Diagnosis of VC at initial presentation and biopsy is extremely challenging given overall bland cytomorphology and shared features with reactive verrucoid hyperplastic lesions
 - Recurrence of tumor at a future time may be the diagnostic clue to diagnosis of VC.

Differential Diagnosis

See [Table 16-3](#).

- “Conventional” squamous cell carcinoma:
 - Differentiation of VC from a “conventional” type of carcinoma is based on the presence or absence of cytologic abnormalities (i.e., dysplasia).
 - Any dysplastic epithelial changes should raise serious concern for the possible diagnosis of conventional SCC and exclude a diagnosis of VC although recent classification suggested a category of VC with epithelial dysplasia or invasion ≤ 2 mm in depth from nearest VC area (referred to as VC with dysplasia or minimal invasion).
 - Hybrid neoplasms composed of VC and coexisting conventional SCC occur (see above).
- Proliferative verrucoid leukoplakia (PVL):
 - PVL and verrucous hyperplasia represent interrelated and irreversible mucosal lesions of the oral cavity and upper aerodigestive tract with a

propensity to progress to either VC or conventional types of squamous cell carcinomas:

- Considered premalignant lesion
- Rare aggressive form of oral leukoplakia with a tendency to recur, often with multifocal oral involvement, and to undergo malignant transformation
- Most common in women (4:1), mean age in eighth decade of life, and long history (decades) of oral leukoplakia
- Most commonly begins on the buccal mucosa followed by the hard and soft palate, alveolar mucosa, tongue, floor of mouth, gingiva, and lip
- Cause:
 - No specific risk factors associated with development of PVL
 - History of tobacco use present in a high percentage of patients (greater than 50%) but a significant minority of patients have no history of tobacco use
 - No relationship to HPV or EBV
- Clinical and pathologic appearance in the early stages of PVL no different from any other type of leukoplakic lesion, making diagnosis of PVL in its early stages virtually impossible
- Clinically, lesion is flat, thickened keratosis with the histologic appearance of a nondysplastic keratosis; with progression of disease, the lesions become multiple, multifocal, and confluent with an exophytic and/or warty (verrucoid) appearance; it is in the latter clinical form that squamous cancer (verrucous carcinoma or conventional squamous cell carcinoma) is seen.
- Any given lesion may show a combination of verrucous hyperplasia, verrucous carcinoma, and conventional well-differentiated squamous cell carcinoma.
- Given the fact that PVL is associated with VC in a high percentage of cases, some authors believe that PVL should be considered as a premalignant condition or an early biologic form of VC:
 - This consideration would then obviate the confusion, clinically and pathologically, that surrounds the use of the term verrucous hyperplasia in describing these oral cavity lesions.
- Histology of PVL (see Section 2 for images) includes:
 - Composed of hyperplastic squamous epithelium with regularly spaced, verrucous epithelial projections and associated hyperkeratosis
 - Sharply defined lesion and in contrast to the downward growth into the underlying submucosal compartment by the bulbous rete pegs in VC, hyperplastic epithelium in PVL remains superficial (without submucosal invasion) and does not extend deeper than that of the

adjacent epithelium; this raises the issue of adequate sampling and the difficulties in differential diagnosis on incisional biopsy material.

- To exclude the presence of submucosal invasion, complete excision of the lesion allowing for histologic examination of the entire lesion is most appropriate.
- Treatment of PVL is by surgical excision.
- Disease-free survival rates after surgery are low due to recurrence and multifocal involvement.
- Radiotherapy has not been shown to be effective in controlling disease.
- Keratotic squamous papilloma
- Reactive keratosis and epithelial hyperplasia
- Pseudoepitheliomatous hyperplasia
- Verruca vulgaris
- Keratoacanthoma (when verrucous carcinoma affects cutaneous sites)

Treatment and Prognosis

- Surgery is the preferred therapeutic modality for VC of all sites:
 - In larynx extent of surgery depends on clinical stage:
 - T1: laser excision
 - T2: hemilaryngectomy
 - T3, T4: total laryngectomy
- Radiotherapy can be used in selected cases:
 - May be used in patients with advanced disease and/or in patients who are not good surgical candidates
 - Previous reason cited for not irradiating VC is purported induction of anaplastic transformation of VC after radiotherapy.
 - Reported VC treated by radiation that underwent anaplastic transformation more likely did not represent VC but represented hybrid carcinomas or pure conventional SCC misdiagnosed as VC.
- Prognosis is excellent after complete surgical removal.
- Local recurrence may occur if incompletely excised.
- Therapy and prognosis for VC with epithelial dysplasia or minimal invasion appears to be similar to (pure) VC than to hybrid carcinoma.
- Cervical adenopathy may be associated with VC, representing reactive changes and not metastatic disease:
 - Neck dissection generally not warranted in treatment
 - Hybrid carcinomas have potential to metastasize.
 - Hybrid carcinomas should be staged and managed as conventional squamous cell carcinomas.
- Distant metastases do not occur
- Death due to disease occurs in approximately 4% of cases:
 - Due to local uncontrollable disease

Spindle Cell (Squamous) Carcinoma (SCSC)

(Figs. 16-41 through 16-50)

Definition: Biphasic variant of squamous cell carcinoma composed of conventional squamous cell carcinoma (in situ or invasive carcinoma) associated with a malignant spindle-shaped and pleomorphic (epithelioid) component.

Synonyms: “Sarcomatoid” carcinoma, carcinosarcoma, pleomorphic carcinoma, metaplastic carcinoma, collision tumor, pseudosarcoma, Lane tumor

Clinical

- Considered uncommon
- Overwhelming majority occur in men (85%); most frequent in sixth through eighth decades of life
- Can occur anywhere in upper aerodigestive tract, but most common sites of occurrence include larynx and oral cavity:
 - Larynx:
 - True vocal cords > false vocal cords and supraglottis
 - Oral cavity:
 - Lips, tongue, gingiva, floor of mouth, buccal mucosa
 - Other sites include:
 - Oropharynx (tonsil, base of tongue), hypopharynx, sinonasal tract, nasopharynx
- Symptoms vary according to site:
 - Larynx: hoarseness, voice changes, airway obstruction, dysphagia
 - Oral cavity: mass or nonhealing sore with or without pain
 - Oropharynx, hypopharynx, sinonasal tract. and nasopharynx: airway obstruction, pain, epistaxis, discharge, facial deformity, unilateral otitis media, orbital symptoms
- Cause:
 - Associated with tobacco use (cigarette smoking)
 - May occur in areas of prior irradiation:
 - Radiation-induced carcinoma
 - Prior radiation used in treatment of other mucosal-based carcinomas
 - Not associated with transcriptionally active HPV:
 - Limited numbers of oropharyngeal cases shown to harbor transcriptionally active, high-risk HPV; HPV may be identified in both conventional and spindle cell components.
- Histogenesis of the spindle cells is controversial as evidenced by the array of names given to this tumor:
 - Epithelial derivation is supported by:
 - Intimate association with conventional squamous cell carcinoma

Fig. 16-41.

A, Laryngeal spindle cell squamous carcinoma endoscopically appearing as a polypoid mass protruding into and partially obstructing the laryngeal lumen.
B, Autopsy specimen of a large, solid laryngeal spindle cell carcinoma completing obstruction of the airway.

Fig. 16-42. Histology of SCSC.

A, B, The diagnostic histologic features of spindle cell squamous carcinoma include the presence of differentiated squamous cell carcinoma in the form of intraepithelial dysplasia/carcinoma in situ and/or invasive squamous cell carcinoma and associated undifferentiated malignant spindle-shaped and pleomorphic cell proliferation. Note the intimate association of the differentiated squamous cell carcinoma and the malignant spindle cell component.

- Presence of cytokeratin immunoreactivity in the majority of cases and absence of immunoreactivity with other antibodies
- Ultrastructural evidence of epithelial differentiation
- Tendency to metastasize to lymph nodes rather than viscera by hematogenous routes supports carcinomatous nature
- Epithelial tropism of HPV infection confirms the epithelial nature of the spindle cell component.

Pathology

Gross

- Polypoid or fungating mass commonly found in the larynx, hypopharynx, oral cavity, and sinonasal tract
- Variations in the gross appearance may correlate with the primary site of occurrence:

Fig. 16-43. Histology of SCSC.

In spindle cell squamous carcinoma the undifferentiated malignant cell component may include (*left*) spindle-shaped cells and/or (*right*) pleomorphic (epithelioid) cells. Mitotic figures including atypical mitoses can be identified.

- Larynx: polypoid or exophytic
- Other sites: fungating and/or ulcerative
- Firm, tan-white, gray, or pink mass varying in size from 1 to 6 cm

Histology

- Histologic features that define SCSC include the identification of a malignant undifferentiated spindle cell and pleomorphic cellular proliferation and the presence of a conventional squamous cell component.

Differentiated Squamous Cell Component

- Includes either intraepithelial dysplasia and/or frankly invasive squamous carcinoma (typically keratinizing and of varying differentiation)
- Squamous cell component may be limited, requiring multiple sectioning for identification or it may be absent in a given lesion:
 - Surface ulceration with associated fibrinoid necrosis, granulation tissue, and mixed acute and chronic inflammation may be present.
 - Reactive (nonneoplastic) myofibroblastic cell component as part of the inflammatory cell response may be present.

Spindle Cell Component

- Spindle-shaped and/or pleomorphic (epithelioid) cellular components generally represent dominant cell type.
- Growth pattern varies including fascicular, storiform, or palisading and may include an associated collagenized to myxoid-appearing stroma.
- Generally is hypercellular and pleomorphic with large, hyperchromatic nuclei, prominent nucleoli,

Fig. 16-44. Histology of SCSC.

Some examples of spindle cell squamous carcinoma lack a differentiated epithelial component and are entirely composed of an undifferentiated spindle-shaped cellular proliferation with a storiform and/or fascicular growth. These histologic findings coupled with absence of immunoreactivity for epithelial markers and possible presence of immunoreactivity for mesenchymal markers may suggest a diagnosis of a sarcoma. In spite of these findings, the presence of a polypoid (superficial) mucosal-based mass is a feature of carcinomas, including spindle cell squamous carcinoma and not typically one associated with a mucosal-related sarcoma.

many mitoses, including typical and atypical forms:

- Multinucleated giant cells may be present.
- Necrosis is not uncommon.
- Hypocellular collagenized variant:
 - Spindle cell proliferation may be sparsely cellular (hypocellular) with marked stromal collagenization.
 - Even in presence of limited cellularity there is still nuclear pleomorphism and mitotic figures, including atypical mitoses.
- Heterologous elements can be seen including bone and cartilage and may include:
 - Benign bone (osteoid) and/or cartilage

Fig. 16-45. Collagenized or hypocellular SCSC.

Collagenized and hypocellular variant of spindle cell squamous carcinoma shows a prominent collagenized stroma with varying but less cellularity as compared with more usual type of spindle cell squamous carcinoma. Despite the relative hypocellularity, the cells are markedly pleomorphic and atypical mitotic figures are identified.

- May include malignant bone (osteosarcomatous) and/or malignant cartilage (chondrosarcomatous) foci
- Rhabdomyosarcomatous elements may rarely be present:
 - Rhabdomyoblasts identified
 - Myogenic markers including desmin, myogenin, and myoglobin are positive.
- Histochemical stains:
 - Essentially noncontributory to the diagnosis
- Immunohistochemistry:
 - Spindle cells are cytokeratin immunoreactive in the majority of cases but may be absent in up to 40% of cases.
 - Broad spectrum of cytokeratin staining should be used, including:
 - Pancytokeratin (AE1/AE3), CAM5.2, CK5/6, OSCAR, CK18, CK903
 - May vary from focal to diffuse
 - Absence of cytokeratin staining does not preclude a diagnosis of spindle cell squamous carcinoma.
 - p63 (nuclear) immunoreactivity often mirrors cytokeratin reactivity but may be positive in cases lacking cytokeratin staining:
 - Transcription factor consistently expressed in normal squamous epithelium and in squamous cell carcinoma
 - Recognizes DNp63 and TAp63 isoforms of the p63 molecule
 - May be positive in soft tissue tumors and reactive stromal proliferations
 - p40 (nuclear) immunoreactivity may be present:
 - Recognizes only squamous-specific isoform DNp63
 - Less consistently positive than p63
 - Less likely to be positive in soft tissue tumors and reactive stromal proliferations

Fig. 16-46. SCSC with features suggesting inflammatory myofibroblastic tumor (IMT).

SCSCs may coexist with a reactive myofibroblastic proliferation or may have features suggesting a myofibroblastic dominant lesion (e.g., IMT), including **(A)** polypoid mass with a granulation tissue-like appearance; **(B through D)** cells with basophilic to eosinophilic fibrillar-appearing cytoplasm, some with axonal extensions, with or without an associated inflammatory cell infiltrate. Although myofibroblastic dominant lesions may have increased mitotic activity, the presence of atypical mitoses (not shown) would be a feature associated with malignancy.

- Vimentin reactivity consistently identified in all cases:
 - Diffuse and strongly reactive
- Various myogenic markers, including desmin and actins, may be present:
 - Coexpression of mesenchymal markers and epithelial markers (i.e., cytokeratin) may occur.
 - Expression of myogenic markers could correlate to presence of myofibroblastic cells as a reactive proliferation as part of wound healing secondary to ulceration.
 - In the absence of rhabdomyoblastic differentiation, other myogenic markers including myogenin and myoglobin typically are not present.
- S100 protein and melanoma-related markers (HMB-45, melan-A, tyrosinase, MITF1, Sox10) are negative.
- p16 positivity may be present in a minority of cases:
 - Positive cases tend to be located in oropharynx.
 - Rare in nonoropharyngeal locations
- Electron microscopy:
 - Majority of cases show evidence of epithelial derivation, including desmosomes, tonofilaments, macula adherens.
 - Considered less sensitive in comparison to immunohistochemistry in identifying epithelial differentiation
- Cytogenetics and molecular genetics:
 - Identical (immunohistochemical) p53 expression patterns in the epithelial and spindle cell components support concept that these phenotypically divergent cell populations share similar developmental pathways and divest concept that SCSC represents a reactive process or a collision tumor between epithelial and mesenchymal components

Fig. 16-47. Heterologous elements in SCSC.

Heterologous elements that may be found in spindle cell squamous carcinoma include **(A)** osteoid and **(B)** osteosarcomatous foci. Additional heterologous components that can be found in spindle cell squamous carcinoma include chondroid and chondrosarcomatous foci (not shown). **C** and **D**, Rhabdomyosarcomatous differentiation can on rare occasions be seen in association with SCSC manifested in the form of spindle-shaped strap cells lying just below the surface squamous epithelium confirmed by **(E)** desmin and **(F)** myogenin (nuclear) immunoreactivity.

Fig. 16-48. IHC in SCSC.

The immunohistochemical (IHC) antigenic profile of spindle cell squamous carcinoma may include **(A)** cytokeratin (AE1/AE3); **(B)** CAM 5.2 (low molecular weight keratin); **(C)** CK 5/6; **(D)** p63 (nuclear stain); **(E)** vimentin; **(F)** smooth muscle actin; **(G)** desmin (right panel).

Fig. 16-49. Metastatic SCSC.

Nodal metastasis in spindle cell squamous carcinoma may include the differentiated epithelial component only, the spindle cell component only, or both. (**A** and **B**) This cervical neck nodal metastasis that occurred in a patient with a laryngeal spindle cell squamous carcinoma was entirely composed of a malignant spindle cell component. **C**, The neoplastic cells were focally cytokeratin (AE1/AE3) positive.

- Varying findings reported on the presence of high-risk HPV in SCSC:
 - Majority of SCSC of head and neck, including those arising in the oropharynx, are not related to transcriptionally active HPV
 - A few p16-positive oropharyngeal SCSCs shown to harbor HPV16 by DNA in situ hybridization but HPV not detected in p16-positive nonoropharyngeal lesions:
 - In HPV-positive tumors, HPV identified in both conventional and spindle cell components
- Significant downregulation of miR-200 family and miR-205, loss of desmosomal cadherins, and altered expression of classic cadherins in SCSC reported in comparison with conventional squamous cell carcinoma:
 - Downregulation of miR-200 family and miR-205 strongly supports the postulated role of epithelial-mesenchymal transition in spindle cell squamous carcinoma.
- Altered expression of cadherin-catenin complex associated with morphologic transition from epithelial to spindle cell phenotype:
 - Reminiscent of epithelial-mesenchymal transition (EMT)
 - Supports role of EMT in pathogenesis of SCSC, which is further supported by presence of Snail-1 expression, a potent inducer of EMT, in cases of SCSC
- Studies on mouse model developed in SCSC showed:
 - Marked downregulation of epithelial differentiation markers and cell adhesion genes
 - Inhibition in expression of growth factors and receptors important for epithelial proliferation with increase in expression of growth factors and receptors that regulate fibroblast and mesenchymal cell proliferation
 - Largest class of upregulated genes in SCSC was chemokine receptors and ligands involved in tumor cell invasion and metastasis.

Fig. 16-50. Laser resection of polypoid SCSC.

A, Polypoid spindle cell squamous carcinoma; such a tumor with polypoid growth and limited invasive component could potentially be treated by conservative surgery to include polypectomy with tumor free margins. **B**, Example of a patient with a vocal cord polypoid spindle cell squamous carcinoma treated by laser excision (polypectomy); intraoperative consultation (frozen section) identified the absence of carcinoma at the deep surgical margins (not shown). **C**, Postlaser removal. On long-term follow-up (>5 years), this patient has been free of tumor (recurrence or progression).

- Above changes in gene expression show loss of epithelial characteristics, acquisition of mesenchymal phenotypes, and increased propensity for invasion and metastasis by SCSC.

Differential Diagnosis

See [Table 16-3](#).

- Reactive lesions (e.g., contact ulcers), reactive myofibroblastic lesions (e.g., nodular fasciitis), and inflammatory myofibroblastic tumor (IMT):

- These lesions are moderately cellular with a proliferation of spindle-shaped cells but do not display a striking degree of nuclear pleomorphism.
- Mitotic figures may be encountered but atypical mitoses are not seen; the findings of atypical mitoses should prompt consideration of a true malignancy.
- Although these lesions are not encapsulated, they do not exhibit the insidious pattern of infiltration of adjacent tissues, which is characteristic of more aggressive lesions, such as SCSC.

- May fill the submucosal region, abutting the basement membrane on which the mucosal epithelial cells are resting; however, the spindle cell proliferation does not infiltrate into the mucosal epithelial cells; nevertheless, the overlying mucosa may appear atrophic in areas.
- Typically are cytokeratin, p63, and p40 negative:
 - Cytokeratin or p63 reported in IMT and granulation tissue
- Myofibroblastic cells may be muscle-specific actin (HHF35), smooth muscle actin, and vimentin positive.
- Cells of IMT may be ALK1 positive, a feature not identified in SCSC.
- Postradiation changes:
 - Radiation (myo)fibroblasts may raise concern for presence of malignant spindle cells.
 - Radiation (myofibroblasts) may be cytokeratin and p63 positive.
 - Tend to occur in association with other radiation-associated histologic changes
- Subglottic stenosis
- Sarcomas:
 - Sarcomas of the mucosal surfaces of the head and neck in general and the larynx in specific (except for chondrosarcoma), including undifferentiated pleomorphic sarcoma, fibrosarcoma, malignant peripheral nerve sheath neoplasm, synovial sarcoma, and others, are rare.
 - In general, mucosal-based sarcomas of the upper aerodigestive tract are deeply seated in any given location and do not usually result in a polypoid mass protruding from a mucosal surface.
 - As a rule, in the absence of any other confirmatory studies, a malignant spindle cell neoplasm of a mucosal surface of the upper aerodigestive tract presenting as a polypoid lesion or identified in more superficial locations of the submucosa should be considered as an SCSC; the latter is true even in the absence of a squamous carcinomatous component, the presence of heterologous matrix-producing elements, absence of cytokeratin immunoreactivity and presence of mesenchymal type markers.
- Mucosal malignant melanoma
- Radiotherapy may be used as an adjunct to surgery but neither radiotherapy nor chemotherapy has merit as sole therapeutic modality:
 - Reports of patients with early-stage SCSC of the glottis (i.e., T1 and T2 lesions) treated with radiation in a similar manner as early-stage conventional squamous cell carcinoma:
 - Histologic diagnosis of SCSC by itself should not influence the decision to treat a patient with early-stage glottic disease with irradiation.
 - Results show that patients with early-stage glottic SCSC treated by radiation alone had similar control rates to irradiated patients with similar volume disease with the more typical squamous cell carcinoma
- Overall 5-year survival of patients with laryngeal SCSC reported to be 59%
- Prognosis dependent on the clinical stage but, in general, is considered poor:
 - Depth of invasion important prognostic parameter:
 - Minimally invasive tumors better prognosis than tumors with any significant degree of invasion
 - Polypoid lesions with limited presence of limited invasion behave less aggressively than flat, ulcerative, and more deeply invasive tumors:
 - 90% overall 3-year survival reported for patients with glottic polypoid SCSC
 - 44% overall 3-year survival reported for patients with sessile glottic SCSC
 - Polypoid configuration alone does not confer better prognosis but depends on extent of invasion within the polypoid lesion.
 - Size of tumor does not correlate with survival.
- Prognosis also linked to location of lesion:
 - Vocal cord lesions, in particular glottic SCSC, tend to manifest symptoms early in the disease course and have better prognosis than SCSC arising in other sites (supraglottis, hypo-, oro-, and nasopharynx, oral cavity, and sinonasal tract) in which symptoms tend to occur only after the tumor has become large and extensively infiltrative.
- Although number of HPV-positive cases are too small for any definitive conclusions, positive viral status does not appear to confer any prognostic benefit.
- Metastatic disease primarily occurs to cervical lymph nodes and lung and may include:
 - Conventional squamous cell carcinoma alone
 - Spindle cell carcinoma alone
 - Both conventional and spindle cell squamous carcinoma

Treatment and Prognosis

- Surgery is the preferred mode of therapy:
 - Often necessitates radical extirpation
 - Conservative (limited) surgery such as polypectomy can be performed in limited settings such as the occurrence in an at-risk or poor surgical candidate who has a polypoid lesion and tumor-free margins can be achieved.

Basaloid Squamous Cell Carcinoma (BSCC) (Figs. 16-51 through 16-56)

Definition: High-grade variant of squamous cell carcinoma histologically characterized by an invasive neoplasm predominantly composed of basaloid-appearing cells intimately associated with dysplastic squamous epithelium, in situ squamous cell carcinoma, and/or invasive squamous cell carcinoma.

Synonyms: Basaloid carcinoma; adenoid-cystic-like carcinoma

Clinical

- Occurs more commonly in men than in women; predominantly occurs in the sixth to seventh decades of life
- May occur in any mucosal site of upper aerodigestive tract but tends to predilect to:
 - Hypopharynx (piriform sinus)
 - Larynx (supraglottis)
 - Oropharynx (palatine tonsil, base of tongue)
- Symptoms depend on the site of occurrence and relative to laryngeal tumors include:
 - Hoarseness, dysphagia, pain, or a neck mass
- Cause:
 - Strong association with tobacco and alcohol use:
 - Generally linked to hypopharyngeal and laryngeal lesions
 - Association with human papillomavirus (HPV):
 - Linked with oropharyngeal lesions
 - Referred to as HPV-associated basaloid squamous cell carcinoma of the oropharynx—see Section 3
 - Many but not all of oropharyngeal BSCCs associated with HPV 16

Fig. 16-51. Basaloid squamous cell carcinoma.

Histologic features of basaloid squamous cell carcinoma include **(A)** infiltrating cellular neoplasm with varied growth patterns including lobular, trabecular, and solid; comedonecrosis can be seen in the center of neoplastic lobules; **(B)** “jigsaw” puzzle-like configuration of the neoplastic lobules; **(C)** higher magnification showing juxtaposition of a lobule with comedotype necrosis (left) and adjacent area in which reduplicated basement membrane-like material (right) reminiscent of salivary gland tumors is present; **(D)** a predominant basaloid cell proliferation characterized by nuclear hyperchromasia, marked nuclear pleomorphism, increased mitotic activity, and individual cell necrosis; peripheral nuclear palisading is present, usually focally, but without retraction artifact of adjacent stroma as occurs in cutaneous basal cell carcinomas.

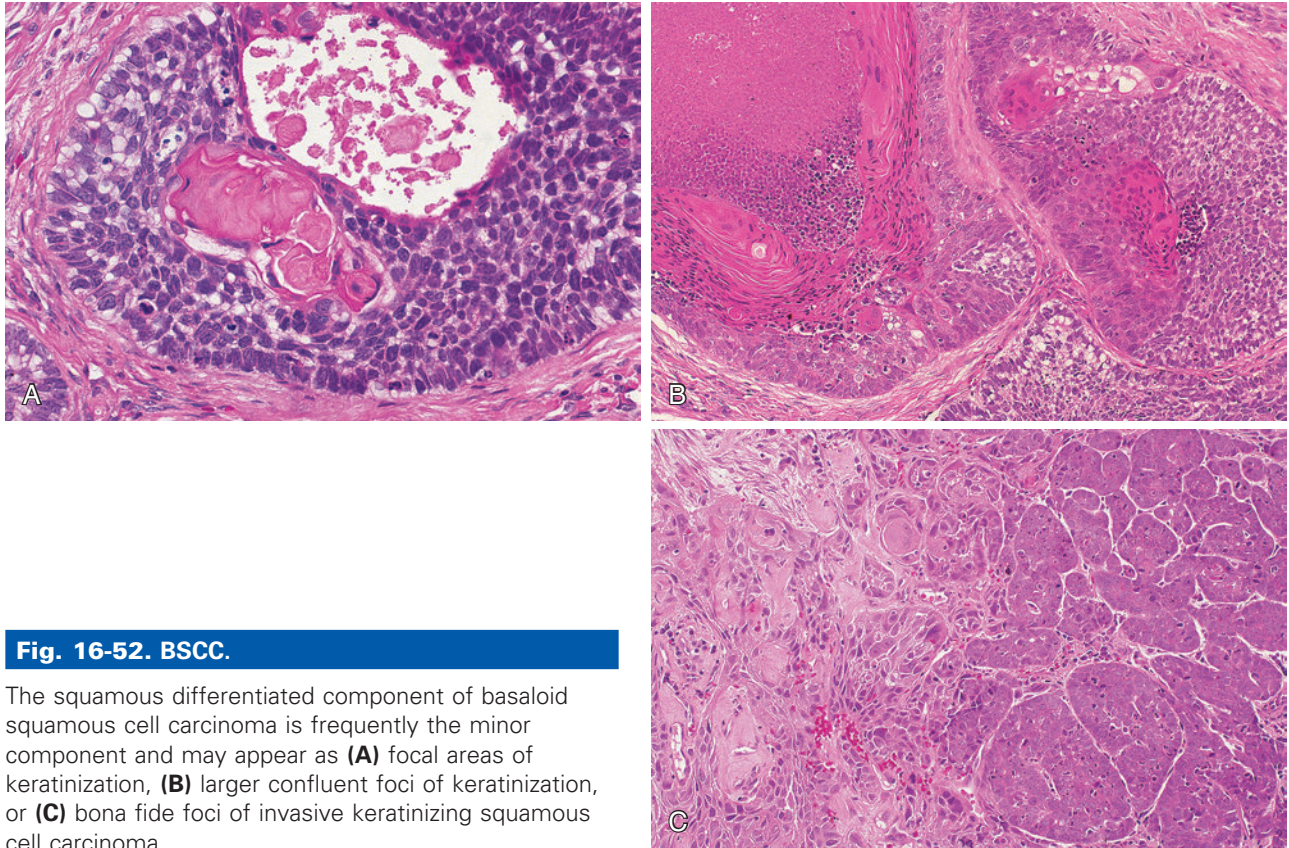

Fig. 16-52. BSCC.

The squamous differentiated component of basaloid squamous cell carcinoma is frequently the minor component and may appear as **(A)** focal areas of keratinization, **(B)** larger confluent foci of keratinization, or **(C)** bona fide foci of invasive keratinizing squamous cell carcinoma.

- HPV-associated basaloid squamous cell carcinoma of the oropharynx:
 - Predilect to base of tongue > tonsil
 - More common in men than women
 - p16 positive and presence of transcriptionally active HPV
 - Confers a better prognosis than non-HPV-associated BSCC
- Increasing evidence identifying the presence of HPV in association with BSCC of the head and neck (see later under Genetics and Cytogenetics)
- Cell of origin has not definitively been identified but in all probability is a single totipotent cell capable of divergent differentiation and located either in the basal cell layer of the surface epithelium or within seromucous glands.

Pathology

Gross

- Firm to hard, tan-white mass often with associated central necrosis measuring up to 6.0 cm in greatest dimension
- Infrequently, may be exophytic in appearance.

Histology

- Invasive neoplasm composed of basaloid cells with an associated squamous component demonstrating

variety of growth patterns, including solid, lobular, cribriform, cords, trabeculae, and gland-like or cystic growth.

Basaloid Cell Component

- Predominant cell type consists of cells with pleomorphic, hyperchromatic nuclei, scanty cytoplasm, and increased mitotic activity:
 - Peripheral nuclear palisading may be present.
- Comedonecrosis may be seen in the center of neoplastic lobules.
- Direct continuity with surface epithelium may be present:
 - Surface epithelium in direct continuity with invasive basaloid component may or may not show intraepithelial dysplasia.
- Interstitial deposition of a hyalin or mucohyalin material can be seen:
 - Similar appearance to reduplicated basement membrane material seen in some salivary gland tumors
 - May impart cribriform-type growth pattern
- Gland-like spaces may be present:
 - May contain mucinous or hyalinized material
- Cells with clear-appearing cytoplasm may be seen either focally or more extensively.

Fig. 16-53. BSCC with high-grade intraepithelial dysplasia/CIS.

A, B, High-grade intraepithelial dysplasia/CIS is a frequent feature seen in association with basaloid squamous cell carcinoma.

Fig. 16-54. Other findings in BSCC.

Morphologic variations that can be seen in association with basaloid squamous cell carcinoma include **(A)** spindle-shaped cells with storiform growth; **(B)** rosettes; **(C)** clear cells; **(D)** clear cells contain glycogen as evidenced by the presence of *(left)* periodic acid Schiff–positive intracytoplasmic material that is cleared by *(right)* diastase digestion.

Fig. 16-55. Infiltrative growth in BSCC.

Basaloid squamous cell carcinomas often are extensively infiltrative, including the presence of **(A)** neurotropism and **(B)** endothelial-lined (arrows) lymph-vascular space invasion and **(C)** deep invasion into skeletal muscle.

- Additional findings may include:
 - Spindle cell component may be identified:
 - Usually very limited in extent and does not predominate
 - Rare examples in which the spindle cell component may predominate
 - Features diagnostic for BSCC still present
 - Infrequently, true neural-type rosettes may be present.
 - Extracellular calcifications may be present.

Squamous Cell Component

- Typically, represents minor component and may be focally present:
 - In biopsies squamous cell component may be absent.
- Squamous cell component may variably include:
 - Dysplastic squamous epithelium and/or carcinoma in situ (CIS)
 - Invasive differentiated squamous cell carcinoma characterized by presence of intercellular bridges, keratin pearl formation, and/or individual cell keratinization (cells with abundant eosinophilic cytoplasm)
 - Foci of abrupt keratinization
- Histologic features (growth patterns and cell types) are same whether associated with or not associated with HPV:
 - Presence or absence of HPV represents key feature in distinguishing these tumor types.
- Histochemistry:
 - Diastase-sensitive, periodic acid Schiff–positive intracytoplasmic material indicative of glycogen

Fig. 16-56. BSCC: differential diagnosis.

The differential diagnosis of basaloid squamous cell carcinoma, especially in biopsy material, includes adenoid cystic carcinoma and small cell neuroendocrine carcinoma. The presence of a basaloid cell proliferation with **(A)** pseudocystic spaces and **(B)** reduplicated basement membrane material in these examples of basaloid squamous cell carcinoma can suggest a diagnosis of adenoid cystic carcinoma. **C**, However, the presence of *(left panel)* marked nuclear pleomorphism with increased mitotic activity seen in basaloid squamous cell carcinoma contrasts with the *(right panel)* isomorphic, small angulated basaloid cells lacking pleomorphism and mitotic activity as seen in usual types of adenoid cystic carcinomas. **D**, Further, the presence of *(left panel)* squamous differentiation in basaloid squamous cell carcinoma is a finding not identified in *(right panel)* adenoid cystic carcinoma. In addition, adenoid cystic carcinomas show the presence of true glandular differentiation, a feature not seen in basaloid squamous cell carcinoma (not shown). The absence of staining for neuroendocrine markers assists in differentiating basaloid squamous cell carcinoma from small cell neuroendocrine carcinoma.

- may be present, especially in cells with clear cytoplasm.
 - Alcian blue–positive material may be present within the cystic spaces.
- Immunohistochemistry:
 - Consistently reactive for cytokeratins (AE1/AE3, CAM5.2, CK5/6, CK903, OSCAR):
 - Do not show punctate paranuclear reactivity seen in small cell neuroendocrine carcinoma
 - p63 diffusely and strongly reactive
 - EMA positive in majority of cases
 - CEA may be positive and tend to be limited to squamous component.
 - CD56 reactive:
 - Not sensitive or specific marker for neuroendocrine differentiation
 - Neuroendocrine markers (i.e., chromogranin and synaptophysin) usually negative but occasional cases may be (focally) synaptophysin positive
 - Variable expression for vimentin, NSE, S100 protein, and smooth muscle actin:
 - Numerous S100 protein dendritic cells can be seen.
 - CD117 negative
 - Melanoma markers (e.g., HMB-45, melan-A, tyrosinase, MITF1, Sox10) negative

- May be p16 positive:
 - Typically seen in association with oropharyngeal tumors
- Electron microscopy:
 - Features of squamous cell carcinoma are present, including cell groups with numerous and prominent tonofilament bundles, increased desmosomes, and epithelial pearls and loose stellate granules or replicated basal lamina within the cystic spaces and absence of glandular differentiation.
- Cytogenetics and molecular genetics:
 - Increasing evidence identifying HPV in association with oropharyngeal BSCC:
 - High-risk HPV identified by in situ hybridization or PCR
 - MYB-NFIB gene fusion:
 - Absent in BSCC
 - Present in adenoid cystic carcinoma

Differential Diagnosis (Tables 16-3 and 16-4)

- Shallow biopsies may belie the depth and extent of invasion and may not be representative of the lesion, leading to erroneous classification.
- Adenoid cystic carcinoma
- Adenosquamous carcinoma
- Small cell undifferentiated neuroendocrine carcinoma
- Olfactory neuroblastoma (for sinonasal tract BSCC)

Treatment and Prognosis

- Preferred treatment includes radical surgical excision, neck dissection, and combined radiation and chemotherapy:
 - As result of early regional lymph node and distant visceral metastases, radical neck dissection and supplemental radio- and chemotherapy may be included in the initial management protocol.
- Aggressive, high-grade tumor with increased tendency to be multifocal, deeply invasive, and metastatic:
 - Metastases occur via lymphatics and blood vessels with sites of predilection including regional and distant lymph nodes, lung, bone, skin, and brain.
 - Metastases include basaloid and squamous cell components.
- Associated with increased incidence of second primary malignancy in upper aerodigestive tract
- Initially considered to be rapidly fatal neoplasm associated with high mortality rates within the first year after diagnosis and believed to be more aggressive than conventional SCC when matched stage for stage
 - Likely correlated to tendency to present with advanced clinical stage disease

- More recent data suggest stage for stage, prognosis similar to that for conventional SCC:
 - Compared with SCC, BSCC not shown to be an independent adverse prognostic factor for patients with head and neck cancer
 - BSCC histology does not have independent adverse prognostic effect on overall survival.
- HPV-positive BSCCs as compared with HPV-negative BSCCs:
 - Have improved overall survival
 - May be due to increased radiosensitivity of HPV-positive tumors
 - Explains lower hazard ratio for death in patients with oropharynx BSCC

Adenosquamous Carcinoma (ASC) (Figs. 16-57 through 16-59)

Definition: Malignant high-grade surface epithelial-derived neoplasm with histologic features of a squamous cell carcinoma and adenocarcinoma.

Clinical

- Rare neoplasm
- More common in men than in women; occur over a wide age range but are most frequently seen in the sixth to seventh decades of life
- May occur in virtually all upper aerodigestive tract sites but is identified most frequently in the larynx, hypopharynx, and less often in the oral cavity (tongue, floor of mouth, palate), oropharynx (tonsil, base of tongue) and sinonasal cavity
- Symptoms vary according to the site of occurrence:
 - Larynx: dysphagia, hoarseness, a mass with or without pain

Fig. 16-57. Adenosquamous carcinoma.

Supraglottic exophytic and ulcerated neoplasm that proved to be an adenosquamous carcinoma.

TABLE 16-4 Basaloid Squamous Cell Carcinoma: Differential Diagnosis

	BSCC	AdCC	SCUNC
Age/Gender	6th-7th decades; M > F	5th-7th decades; no gender predilection except for submandibular tumors, which predilect to women	6th-7th decades; M > F
Location	Predilects to hypopharynx (piriform sinus), larynx (supraglottis), and oropharynx (tonsils, base of tongue)	Major salivary glands and minor (intraoral) minor salivary glands; may occur in other mucosal sites including sinonasal tract; rare in the larynx and hypopharynx	Uncommon in H&N: larynx (supraglottis) is the most common site; other H&N sites rare and may include sinonasal tract and parotid gland
Histology: 1. Growth 2. Cytomorphology	1. Invasive lobules with comedotype necrosis, solid, cords, trabeculae gland-like; cribriform pattern may be seen but tends to be limited; intercellular basement- membrane-type material may be present 2. Composed predominantly of pleomorphic, hyperchromatic basaloid cells with numerous mitoses; squamous cell component (dysplasia, CIS, invasive SCC) is the minor component; neural-type rosettes rarely may be present	1. Invasive with cribriform growth (representing the most frequent pattern), tubular/glandular, solid; pseudocysts present 2. Composed predominantly of abluminal (myoepithelial) cells composed of isomorphic cells with hyperchromatic (basaloid) angular to oval nuclei, absent to small nucleoli, eosinophilic to clear- appearing cytoplasm lacking nuclear pleomorphism and mitotic activity; in addition, luminal (duct) epithelial cells present lining true glandular spaces characterized by the cells with round nuclei and eosinophilic-appearing cytoplasm	1. Submucosal invasive tumor with solid nests, sheets or ribbons and absence of a fibrovascular stroma 2. Hypercellular tumor with hyperchromatic, pleomorphic, oval to spindle-shaped nuclei, increased nuclear-to- cytoplasmic ratio, nondescript cytoplasm, and indistinct cell borders; nuclear chromatin described as “salt and pepper” in appearance with absence of nucleoli; “crush” artifact is frequently present; confluent foci of necrosis and individual cell necrosis seen; abundant mitoses, including atypical forms; nuclear molding may be identified; neural-type rosettes may be present
Surface involvement	Present in the form of dysplasia or CIS	Absent	Absent but surface may be ulcerated
Squamous differentiation	Present but is the minor component and may only focally be found	Absent	Present but when found is typically limited in extent
Neurotropism	Yes	Yes	Yes
IHC	Diffuse and strong reactivity for cytokeratins and p63; neuroendocrine markers (e.g., synaptophysin, others) usually negative but occasionally may be positive; p16 typically negative in nonoropharyngeal sites and may be positive in oropharyngeal tumors	Abluminal cells: positive for cytokeratins, p63, S100 protein, calponin, SMA, SMMS, vimentin Duct cells: positive for cytokeratins, EMA, CEA, CD117 All cell types negative for neuroendocrine markers (chromogranin and synaptophysin)	Positive for cytokeratins often with punctate paranuclear pattern; CK5/6 usually negative; p63 may be positive but usually not as consistently positive as seen in BSCC and AdCC; neuroendocrine markers (e.g., synaptophysin, others) positive; calcitonin rarely positive
HPV association (transcriptionally active)	Possible*	No	Possible*
Gene fusion	Absent	MYB-NFIB present	Absent
Treatment	Surgery, radiotherapy, chemotherapy	Surgery and radiotherapy	Systemic chemotherapy and therapeutic irradiation

Continued

TABLE 16-4 Basaloid Squamous Cell Carcinoma: Differential Diagnosis—cont’d			
	BSCC	AdCC	SCUNC
Spread	Metastasis frequent often at presentation to cervical lymph nodes and lung	Metastasis (local or distant) uncommon: distant metastasis occurs late in disease course to lungs, bone, brain, and liver	Metastasis frequent (even at presentation) to regional lymph nodes and to liver, lung, bone, and brain
Prognosis	Dependent on clinical stage but overall considered to be poor; HPV-associated share better outcomes similar to oropharyngeal nonkeratinizing (HPV-associated) carcinomas	Short-term prognosis is good but long-term prognosis is poor; survival rates include: 5-year 71% to 89% 10-year 29% to 71% 15-year 29% to 55%	Poor: 16% 2-year survival; 5% 5-year survival Presence of transcriptionally active HPV does not alter poor prognosis

AdCC, Adenoid cystic carcinoma; BSCC, basaloid squamous cell carcinoma; CIS, carcinoma in situ; HPV, human papillomavirus; IHC, immunohistochemistry; SCUNC, small cell undifferentiated neuroendocrine carcinoma.

*BSCC and SCUNC may harbor transcriptionally active HPV especially when of oropharyngeal origin.

Fig. 16-58. Adenosquamous carcinoma.

A, Invasive carcinoma originating from the surface epithelium (*left*) consisting of an admixture of glandular and squamous differentiation. **B**, The glands and squamous foci may be intimately admixed or **(C)** lie adjacent to one another (*left panel* squamous differentiation and *right panel* glandular differentiation). These tumors are high-grade malignancies composed of pleomorphic cells with prominent eosinophilic nucleoli and increased mitotic activity.

Fig. 16-59. Adenoid squamous cell carcinoma.

Adenoid squamous cell carcinoma is characterized by pseudolumen formation due to acantholysis, creating the appearance of gland formation that may suggest a diagnosis of adenosquamous carcinoma.

- Cause:
 - No clearly defined cause
 - May be related to alcohol and/or tobacco use
- Cell of origin not definitively identified but in all probability is a single totipotent cell capable of divergent differentiation and located either in the basal cell layer of the surface epithelium or within mucoserous glands; in the latter, the cell arises from excretory or interlobular salivary gland ducts

Pathology

Gross

- Exophytic or submucosal, friable, edematous, or granular mass with or without surface ulceration measuring from 0.6 to 5.0 cm.

Histology

- Infiltrating cytologically high-grade neoplasm composed of solid nests and glandular growth
- Necrosis and perineural invasion commonly identified

Squamous Cell Component

- Includes invasive SCC and/or high-grade intraepithelial dysplasia/CIS:
 - Squamous cell differentiation evident by the presence of individual cell keratinization, intercellular bridges, keratin pearl formation, and/or dyskeratosis
 - Varies from well to poorly differentiated
 - Often high-grade intraepithelial dysplasia/CIS of surface epithelium is present
 - May extend to seromucous glands
 - Often identified in direct continuity to surface epithelium
- May be admixed with or distinct from adenocarcinomatous component

Adenocarcinoma Component

- Characterized by gland formation with or without complex (gland in gland) growth
- Characterized by presence of moderate to marked nuclear pleomorphism and increased mitotic activity
- Necrosis may be present.
- Typically identified in the submucosa:
 - Usually seen in deeper aspects of the tumor
 - Mucous cell differentiation usually not seen and not a prerequisite for diagnosis
- May be admixed with or distinct from squamous cell carcinomatous component
- Histochemistry:
 - Intracellular and intraluminal mucicarmine and diastase-resistant, PAS-positive material is seen associated with the glandular component.
 - Intracytoplasmic mucin-positive material not typically present
- Immunohistochemistry (both components):
 - Cytokeratin positive, including AE1/AE3, CAM5.2, 34βE12 (CK903) in squamous and glandular components
 - p63 positive in squamous cell component
 - CEA, CK7 positive in glandular component
 - CK20 absent in glandular component
 - High proliferation rates as seen by Ki67 (MIB1) staining
 - Overexpression of p53
- Electron microscopy:
 - Squamous cell carcinoma component:
 - Bundles of tonofilaments, increased desmosomes, and epithelial pearls
 - Adenocarcinoma component:
 - Acini and luminal microvilli
- Cytogenetics and molecular genetics:
 - Absence of *MECT1-MAML2* gene translocation
 - High prevalence of aneuploidy

- Rare examples of ASC with intestinal phenotype reported:
 - Located in hypopharynx
 - Composed of superficial squamous cell carcinoma and adenocarcinoma with intestinal phenotype, the latter showing tubuloglandular and cribriform architecture and immunoreactivity for CK7, CK20, CDX2, CEA, and villin
- HPV-associated ASC:
 - Small minority may be associated with HPV.
 - Locations include oropharynx and sinonasal tract.
 - Histology similar to non-HPV-associated ASCs
 - Overexpression of p16
 - Show active viral transcription with detectable high-risk HPV E6 and E7
 - Appear to be associated with better clinical outcome than non-HPV-associated ASCs

Differential Diagnosis (Table 16-5)

- Mucoepidermoid carcinoma (MEC):
 - Rarely if ever a surface epithelial-derived neoplasm
 - Lacks squamous carcinoma in situ that is typically present in adenosquamous carcinoma
 - Typically lacks evidence of intercellular bridges or keratinization
 - In low-grade and intermediate-grade tumors shows combination of three cell types including mucocytes, epidermoid cells, and intermediate cells
 - Presence of *MECT1-MAML2* gene translocation:
 - Consistently present in low- and intermediate-grade MECs
 - High-grade tumors considered to be MEC but lacking *MECT1-MAML2* gene translocation likely not MECs and may be ASCs
- Adenoid squamous cell carcinoma (see Fig. 16-57):
 - Also referred to as acantholytic squamous cell carcinoma
 - Not a distinct clinical subtype but is a histomorphologic subtype of squamous cell carcinoma
 - Most common in sun-exposed areas of the head and neck; rare tumor of mucosal sites
 - Surface-derived squamous cell carcinoma that is histologically characterized by the presence of pseudolumen formation due to acantholysis, creating the appearance of gland formation; there is no evidence of glandular differentiation either in the form of mucocytes or glands
 - Histochemical stains for epithelial mucin are negative.
 - Cytokeratin, EMA, and p63 strongly positive
 - Absence of endothelial cell-related markers (e.g., CD31, CD34, factor VIII-related antigen, others)
- Prognosis similar to that of squamous cell carcinoma

Treatment and Prognosis

- Radical surgical excision is preferred treatment. As a result of the propensity for this neoplasm to demonstrate early regional lymph node metastasis, radical neck dissection may be necessary as part of the initial management; radiotherapy is of questionable benefit.
- Prognosis is poor as this neoplasm is aggressive and high grade with increased tendency to be multifocal, deeply invasive, and metastatic:
 - These neoplasms behave very aggressively regardless of the size of the neoplasm.
- Metastases occur via lymphatics and blood vessels with sites of predilection, including regional lymph nodes, lung, and liver:
 - Metastatic disease histologically is similar to the primary neoplasm and includes both malignant histologic components.
 - Nodal metastases reported in up to 75% of cases
 - Distant metastases reported in up to 25% of cases
- 5-year survival rates are approximately 15% to 25%.
- 3-year and median overall survival, disease-free survival (DFS), and locoregional control reported to be 52%, 32%, and 47%, respectively.
 - DFS negatively influenced by presence of extracapsular extension and advanced stage
 - Overall prognosis of locoregionally advanced ASC remains poor.
 - Early-stage ASC patients managed with combined modality treatment may have prolonged DFS.
- HPV-associated (oropharyngeal) ASC may have more favorable outcome as compared with non-HPV-associated ASC with longer survival rates:
 - Too few reported cases to clearly determine if these are distinct variant that can be classified according to HPV status.

OTHER UNCOMMON CARCINOMA VARIANTS

Lymphoepithelial-Like Carcinoma (Fig. 16-60)

Definition: Undifferentiated carcinoma with prominent associated benign lymphocytic cell infiltrate that is histologically identical to the more common nasopharyngeal undifferentiated carcinoma.

- See Section 3, Pharynx, for a more complete discussion.
- Rare tumor type of the larynx and trachea

TABLE 16-5 Adenosquamous Carcinoma: Differential Diagnosis

	ASC	MEC, Low- and Intermediate Grade	NS	SCC, Adenoid, or Acantholytic
Architecture/growth	Haphazard, infiltrative growth	Haphazard, infiltrative growth	Retention of lobular architecture	Haphazard, infiltrative growth
Cellular components	Invasive squamous cell carcinoma and adenocarcinoma: 2 components may be intermixed or more often are distinct and separate; adenocarcinoma is gland-forming but without mucocytes	Admixture of mucous, epidermoid, and intermediate; bland cytology; irregular cell nests	Smooth round to oval nests of metaplastic squamous epithelium with bland cytology; may show residual ductal lumina with mucous cells	Nests and cords of squamous cells with irregular outlines and variable amount of cytologic atypia; may entrap residual glands but the tumor itself contains no mucocytes
Cyst formation	Absent	Present: prominent component in low-grade and frequent component in intermediate-grade	Absent	Absent
Keratinization and intercellular bridges	Present	Absent	May be present	Present
Surface epithelium	HGSIL/CIS usually present; direct continuity with the carcinoma; surface may be ulcerated	Submucosal in location when occurs in mucosal sites without involvement (direct continuity) to surface epithelium; ulceration may be present	May show PEH; usually not connected with NS	Often dysplastic and/or in direct continuity with the carcinoma; may be ulcerated
Mucin production	Intraluminal; intracytoplasmic uncommon but may be present	Intracytoplasmic and intraluminal	Retained in residual mucocytes of seromucous glands	Absent
Extravasated mucin	Absent	Present	May be present	Absent
Necrosis	May show tumor necrosis	Absent	Lobular infarction of salivary gland acini	May show tumor necrosis
TALP inflammation	Typically absent although nonspecific chronic inflammation may be present in association with desmoplasia	Often present	Nonspecific chronic inflammation may be present	Typically absent although nonspecific chronic inflammation may be present in association with desmoplasia
Gene fusion	Absent	<i>MECT1-MAML2</i> present	Absent	Absent

ASC, Adenosquamous carcinoma; CIS, carcinoma in situ; HGSIL, high-grade squamous intraepithelial lesion; MEC, mucoepidermoid carcinoma; NS, necrotizing sialometaplasia; PEH, pseudoepitheliomatous hyperplasia; SCC, squamous cell carcinoma; TALP, tumor-associated lymphoid proliferation.

- More common in men than in women; most frequent in the seventh decade of life
- More common in Caucasian populations than in Asian populations
- Tendency to occur in the supraglottic larynx
- Most common symptoms include hoarseness and a neck mass:
 - Less often, sore throat, dysphagia, hemoptysis, and otalgia
- Histology identical to its more common nasopharyngeal counterpart, including:
 - Aggregates or syncytia of neoplastic cells characterized by enlarged vesicular nuclei and prominent nucleoli
 - Foci of squamous cell differentiation including abrupt keratinization of conventional foci of squamous cell carcinoma can be seen.
- Prominent benign lymphocytic cell infiltrate is present; a variable amount of plasma cell may be present.
- Carcinoma in situ of the overlying surface epithelium may be present.

Fig. 16-60. Lymphoepithelial-like carcinoma.

Rare example of laryngeal lymphoepithelial-like carcinoma showing histomorphologic features similar to those of its more common nasopharyngeal counterpart, including neoplastic cells characterized by enlarged vesicular nuclei and prominent nucleoli with variable amount of associated benign lymphoplasmacytic cell infiltrate. In situ hybridization for Epstein-Barr–encoded RNA was negative (not shown).

- Neoplastic cells are immunoreactive for cytokeratins.
- Rarely associated with Epstein-Barr virus
- Risk factors for the development of this carcinoma may include excessive use of tobacco and alcohol.
- Treatment varies and has included limited to radical surgery with adjuvant therapy (radiation and chemotherapy).
- Cervical nodal metastases occurs in a nearly 75% of patients; distant metastases including to the lung, liver, bone, skin occur in approximately 25% of patients.
- Nearly one third of patients reported dead of disease at a 21-month median follow-up.

Giant Cell Carcinoma (Fig. 16-61)

Definition: Undifferentiated carcinoma with many bizarre multinucleated giant cells with or without light

Fig. 16-61. Giant cell carcinoma.

A, B, Upper tracheal malignant neoplasm showing a submucosal proliferation composed of numerous noncohesive multinucleated (osteoclast-like) giant cells with abundant eosinophilic cytoplasm. **C,** Associated smaller malignant cells with increased mitotic activity including atypical mitoses are present. Immunoreactivity for cytokeratins was positive (not shown). Whether this neoplasm represents a distinct entity (i.e., giant cell carcinoma) or a part of another malignant neoplasm remains uncertain.

microscopic evidence of squamous or glandular differentiation, and with intracytoplasmic polymorphonuclear leukocytes or cellular debris.

Synonyms: Large cell carcinoma; pleomorphic carcinoma; anaplastic carcinoma

- By some criteria presence of squamous or glandular differentiation excludes a diagnosis of giant cell carcinoma.
- Diagnosis may be predicated on the quantity of giant cells in a given carcinoma, although various reports cite various percentages of giant cells as qualifying as a giant cell carcinoma.
- Given the fact that when giant cells are seen in squamous cell carcinoma or adenocarcinoma they represent a minor component focally present and are not diffusely present, a carcinoma with a diffuse giant cell population and/or a giant cell component seen in significant quantities should allow classification as a giant cell carcinoma.
- Presence of intracytoplasmic polymorphonuclear leukocytes or cellular debris would further buttress this diagnosis.

Clinical

- Extremely rare
- More common in men than in women; most frequent in the sixth to seventh decades of life
- Occurs in any site of the larynx without predilection to any one location
- Most common symptoms include dyspnea and dysphagia.
- May be linked to cigarette smoking and alcohol use

Pathology

Histology

- Histologically similar to giant cell carcinoma of the lung
- Light microscopy is characterized by:
 - Presence of numerous, noncohesive bizarre-appearing multinucleated giant cells with abundant eosinophilic cytoplasm that may be vacuolated
 - Often contain polymorphonuclear leukocytes or cellular debris
- A background cellular infiltrate that includes smaller anaplastic cells is present.
- Increased mitotic activity including atypical mitoses is present.
- Immunoreactivity for cytokeratin is present.
- May occur in a mixed form in association with squamous cell carcinoma, adenocarcinoma, or spindle cell squamous carcinoma:
 - May be referred to as pleomorphic carcinoma
 - Raises question whether giant cell carcinoma is a specific entity

Differential Diagnosis

- Spindle cell squamous carcinoma
- Sarcomas

Treatment and Prognosis

- Surgery (i.e., partial or total laryngectomy) plus adjuvant therapy (radiation and chemotherapy) is the recommended treatment.
- Increased incidence of cervical nodal metastasis necessitates neck dissection
- Very few reported cases but overall prognosis is poor

LARYNGEAL SALIVARY GLAND MALIGNANT NEOPLASMS

- Malignant salivary gland tumors of the larynx and trachea are rare.
- Although any type of malignant salivary gland tumor may occur in these locations, the most common tumor types are adenoid cystic carcinoma and mucoepidermoid carcinoma.

Adenoid Cystic Carcinoma of the Larynx and Trachea

- Equal gender predilection; occurs over a wide age range but most common in the sixth to eighth decades
- Majority are subglottic followed by the supraglottis
- Symptoms include airway obstruction, dysphagia, hoarseness, sore throat, and pain.
- Histology is similar to adenoid cystic carcinoma of more common locations.
- Differential diagnosis includes basaloid squamous cell carcinoma and small cell undifferentiated neuroendocrine carcinoma (see [Table 16-4](#))
- Surgery is the preferred treatment with postoperative radiotherapy:
 - Given the propensity to occur in the subglottic larynx, a total laryngectomy is often required.
 - Supraglottic tumors may be treated by partial laryngectomy.
- Unless there is clinical evidence of neck disease, a neck dissection would not appear to be warranted.
- Prognosis is similar to adenoid cystic carcinomas of more usual sites.

Mucoepidermoid Carcinoma of the Larynx and Trachea

- More common in men than in women; occurs over a wide age range but most common in the sixth decade:
 - Tracheal tumors may occur in pediatric ages.

- Majority are supraglottic.
- Symptoms include hoarseness, dyspnea, dysphagia, foreign body sensation, and a neck mass.
- Histology is similar to mucoepidermoid carcinomas of more common locations.
- Differential diagnosis includes adenosquamous carcinoma and necrotizing sialometaplasia (Table 16-5):
 - Likely many tumors reported as laryngeal high-grade mucoepidermoid carcinoma with poor prognosis represent adenosquamous carcinoma.
- Surgery is the preferred treatment:
 - Supraglottic tumors may be treated by partial laryngectomy.
- Unless there is clinical evidence of neck disease, a neck dissection for low- and intermediate-grade mucoepidermoid carcinoma is not warranted.
 - Neck dissection is warranted for a diagnosis of high-grade mucoepidermoid carcinoma.
- Prognosis is similar to mucoepidermoid carcinomas of more usual sites:
 - Overall survival rates for all grades of laryngeal MEC are 75% to 80%.
 - For low-grade MEC the 5-year survival rate is 90% to 100%.
 - For high-grade MEC the overall 5-year survival rate is 50% to 55%:
 - As previously noted it is likely that tumors reported as laryngeal high-grade mucoepidermoid carcinoma with poor prognosis represent adenosquamous carcinoma.

LARYNGEAL NEUROENDOCRINE CARCINOMAS

Definition: Heterogeneous group of malignant neoplasms characterized by the presence of neuroendocrine differentiation with prognosis dependent on tumor type.

- In general, an uncommon class of neoplasms in the head and neck.
- May be identified in virtually all sites of the head and neck:
 - Most common: larynx \gg sinonasal tract
 - Less common: salivary glands, pharynx (nasopharynx and oropharynx), oral cavity
- Histologic and immunohistochemical findings similar irrespective of site of origin
- Classification of laryngeal neuroendocrine carcinomas includes (Box 16-5):
 - Carcinoid tumor or well-differentiated neuroendocrine carcinoma (WDNEC)
 - Atypical carcinoid or moderately differentiated neuroendocrine carcinoma (MDNEC)
 - Small cell carcinoma or poorly differentiated neuroendocrine carcinoma (PDNEC) or small

BOX 16-5 Classification of Laryngeal Neuroendocrine Tumors

Benign

- Laryngeal paraganglioma

Malignant

- Carcinoid tumor (well-differentiated neuroendocrine carcinoma)
- Atypical carcinoid (moderately differentiated neuroendocrine carcinoma)
- Small cell undifferentiated neuroendocrine carcinoma (poorly differentiated neuroendocrine carcinoma)
- Large cell undifferentiated neuroendocrine carcinoma (poorly differentiated neuroendocrine carcinoma)

- cell undifferentiated neuroendocrine carcinoma (SCUNC)
- Large cell neuroendocrine carcinoma (LCNEC) subsumed within the broader category of PDNEC
- Order of frequency of occurrence of laryngeal neuroendocrine carcinomas is:
 - Atypical carcinoid (MDNEC) > small cell carcinoma (PDNEC) > carcinoid tumor (WDNEC)

Clinical (as a Group)

- There is much overlap in demographics and clinical features for all subtypes of laryngeal neuroendocrine carcinomas:
 - Histology and prognosis vary per subtype
 - See Tables 16-6 and 16-7 for clinical and pathologic features of laryngeal neuroendocrine carcinomas.
- More common in men than in women; generally occurs in the sixth to seventh decades of life
- Supraglottic larynx is overwhelmingly the most common site of occurrence:
 - May occur less often in the glottis and subglottis
- Hoarseness is most common complaint; other symptoms may include dysphagia.
- History of cigarette smoking linked with atypical carcinoid, small cell carcinoma, and large cell neuroendocrine carcinoma but does not appear to be linked with development of carcinoid tumor

Carcinoid Tumor (Fig. 16-62)

Synonyms: Well-differentiated neuroendocrine carcinoma (WDNEC); typical carcinoid

Clinical

- Least common of the laryngeal neuroendocrine carcinomas
- Generally not associated with smoking history

TABLE 16-6 Clinical Features of Laryngeal Neuroendocrine Tumors

Feature	LP	CT	ACT	SCUNC	LCNEC
Frequency	Rare	Least common	Most common	2nd most common	Uncommon
Age/gender	5th decade; F > M	7th decade (on avg.); M > F	7th decade (on avg.); M > F	6th-7th decades; M > F	Occurs over a wide age range; average age of 59 years M > F
RF	None known	None known	Smoking	Smoking	Smoking
HPV-associated	None known	None known	None known	Possible*	None known
Site	Supraglottis: AE fold and FVC	Supraglottis: AE fold, arytenoid, FVC	Supraglottis: AE fold, arytenoids, FVC	Supraglottis, but may occur elsewhere in the larynx	Supraglottis
Symptoms	Hoarseness; dysphagia, dyspnea, stridor	Hoarseness	Hoarseness	Hoarseness	Hoarseness, dysphagia, otalgia, weight loss; heartburn, cervical adenopathy
Paraneoplastic syndrome	Exceptional; may be multicentric with other H&N paragangliomas	May occur but rare	Rare	Occasional	Unknown
Treatment	Surgery is curative	Surgery	Surgery; adjuvant radiotherapy and chemotherapy	Systemic chemotherapy and therapeutic irradiation	Chemoradiotherapy
Spread	None	Approximately 33% have distant metastases (liver and bone)	Metastasis common to cervical lymph nodes, lung, bone, liver, skin	Metastasis frequent (even at presentation) to regional lymph nodes and to liver, lung, bone, and brain	Commonly present with advanced stage (stages III and IV)
Prognosis	Excellent	Indolent biology with excellent behavior	Fully malignant neoplasm; tumor confined to larynx: 62% median 3.9-yr survival; 48% 5-yr survival; 30% 10-year survival	Poor: 16% 2-year survival; 5% 5-year survival; 5-year disease- specific survival (DSS) of 19%; presence of transcriptionally active HPV does not alter poor prognosis	5-year disease- specific survival (DSS) of 15% to 21%

ACT, Atypical carcinoid tumor; AE fold, aryepiglottic fold; CT, carcinoid tumor; FVC, false vocal cord; LCNEC, large cell neuroendocrine carcinoma; LP, laryngeal paraganglioma; RF, risk factor(s); SCUNC, small cell undifferentiated neuroendocrine carcinoma.

*May harbor transcriptionally active HPV especially when of oropharyngeal origin.

TABLE 16-7 Pathologic Features of Laryngeal Neuroendocrine Tumors

Feature	LP	CT	ACT	SCUNC	LCNEC
Histology	Cell nest or “Zellballen” pattern characteristic of paragangliomas of all sites; cell nests separated by prominent fibrovascular tissue; chief cells (predominant cell) are round or oval with uniform nuclei, dispersed chromatin pattern, and abundant eosinophilic, granular, or vacuolated cytoplasm; sustentacular cells lie at the periphery of the cell nests as spindle-shaped, basophilic-appearing cells but are difficult, if not impossible, to identify by light microscopy	Submucosal tumor with organoid or trabecular growth pattern and fibrovascular stroma; neoplastic cells are uniform with centrally located round nuclei, vesicular chromatin, and eosinophilic cytoplasm; low nuclear-to-cytoplasmic ratio; nuclear chromatin described as “salt and pepper” in appearance with absence of nucleoli; absence of pleomorphism, mitoses, necrosis	Submucosal tumor with organoid, trabecular, cribriform, or solid growth and fibrovascular stroma; neoplastic cells show mild to marked cellular pleomorphism with round to oval nuclei, vesicular to hyperchromatic chromatin, and eosinophilic cytoplasm; nuclei can be centrally or eccentrically located; nucleoli may be prominent; nuclear chromatin described as “salt and pepper” in appearance with absence of nucleoli; mitotic activity present but uncommon; necrosis uncommon	Submucosal tumor with solid nests, sheets, or ribbons and absence of a fibrovascular stroma; hyperchromatic, pleomorphic, oval to spindle-shaped nuclei, increased nuclear-to-cytoplasmic ratio, nondescript cytoplasm and indistinct cell borders; nuclear chromatin described as “salt and pepper” in appearance with absence of nucleoli; “crush” artifact is frequently present; confluent foci of necrosis and individual cell necrosis seen; abundant mitoses, including atypical forms; nuclear molding may be identified; neural-type rosettes rarely may be present	Presence of tumor cells with moderate to abundant cytoplasm, presence of features of neuroendocrine differentiation including organoid nesting, trabecular growth, rosettes, and peripheral palisading; increase mitotic activity (greater than 10 mitoses per 10 high-power fields [2 mm ²])
Infiltration	Absent	Absent	Present including neurotropism	Present including neurotropism	Present including neurotropism; may invade pre-epiglottic space
Angioinvasion	Absent	Absent	Present	Common	Common
IHC	Chief cells positive for neuroendocrine markers (synaptophysin, others) and GATA3; sustentacular cells: S100 protein positive; p63 negative	Positive for cytokeratins and neuroendocrine markers (e.g., synaptophysin, others); may be positive for calcitonin, serotonin, somatostatin, and bombesin; p63 negative; GATA3 negative	Positive for cytokeratin (96%); chromogranin (94%), synaptophysin (100%), calcitonin (80%); also positive for NSE, Leu-7, NFP, EMA, CEA; p63 variably positive and when present tends to be weak; GATA3 negative	Positive for cytokeratins (AE1/AE3) but CK5/6 and 34βE12 typically negative; CK7 and CK20 may be positive for neuroendocrine markers (e.g., synaptophysin, others) NSE, Leu-7, NFP, EMA, CEA, TTF-1; calcitonin rarely positive; GATA3 negative	Neuroendocrine markers positive (e.g., synaptophysin, others); positive for cytokeratin (AE1/AE3) but CK5/6 and 34βE12 typically negative; calcitonin and TTF1 negative
HPV association (transcriptionally active)	No known association	No known association	No known association but identified in a single reported case	Possible*	Not known

ACT, Atypical carcinoid tumor; CEA, carcinoembryonic antigen; CT, carcinoid tumor; EMA, epithelial membrane antigen; LCNEC, large cell neuroendocrine carcinoma; LP, laryngeal paraganglioma; NFP, neurofilament protein; NSE, neuron specific enolase; SCUNC, small cell undifferentiated neuroendocrine carcinoma; TTF-1, thyroid transcription factor 1.

*May harbor transcriptionally active HPV, especially when of oropharyngeal origin with one reported positive case originating in the larynx.

Fig. 16-62. Laryngeal carcinoid tumor.

A, Submucosal cellular tumor. **B** and **C**, Organoid and solid areas composed of uniform cells with centrally located round nuclei, dispersed nuclear chromatin-lacking pleomorphism, mitoses, or necrosis. Immunoreactivity is present for **(D)** cytokeratin (CAM5.2) with paranuclear dot-like staining and **(E)** synaptophysin.

- Carcinoid syndrome may rarely occur in association with carcinoid tumor:
 - Occurs when carcinoid tumor secretes certain chemicals into bloodstream, causing a variety of signs and symptoms
 - Most common in association with carcinoid tumors of the gastrointestinal tract or lungs
 - Typically occurs in patients who have advanced disease
 - Most common signs and symptoms of carcinoid syndrome include:
 - Skin flushing
 - Diarrhea:
 - Frequent watery stools sometimes accompanied by abdominal cramps
 - Rapid heartbeat
 - Difficulty breathing:
 - Asthma-like signs and symptoms (e.g., wheezing and shortness of breath) may occur at same time of skin flushing
 - Facial skin lesions:
 - Purplish spider-like veins may appear on nose and upper lip.
 - Treatment usually involves treating the cancer, but as most carcinoid tumors do not cause carcinoid syndrome until an advanced stage of disease a cure may not be possible:
 - In such cases, medications may relieve symptoms.
 - Medications used are able to block cancer cells from secreting chemicals:
 - Injections of medications octreotide (Sandostatin) and lanreotide (Somatuline Depot) may reduce the signs and symptoms of carcinoid syndrome, including skin flushing and diarrhea.
 - Octreotide may also slow growth of carcinoid tumors.
 - Side effects of octreotide and lanreotide include diarrhea, abdominal pain, and bloating, which may subside over time.

Pathology

Gross

- Submucosal nodular or polypoid mass with a tan-white appearance varying in size from a few millimeters up to 3 cm in diameter
- Surface ulceration is generally absent.

Histology

- Submucosal tumor arranged in organoid or trabecular growth pattern with fibrovascular stroma
- Uniform cells with centrally located round nuclei, vesicular chromatin and eosinophilic cytoplasm; low nuclear-to-cytoplasmic ratio; nuclear chromatin

described as “salt and pepper” in appearance with absence of nucleoli

- Absence of pleomorphism, mitoses, necrosis
- Glands and/or squamous differentiation can be seen.
- Surface ulceration uncommon
- Vascular, lymphatic, and perineural invasion absent
- Histochemistry:
 - Argyrophilic staining (e.g., Churukian-Schenk) positive characterized by presence of intracytoplasmic granular material typically appearing black
 - Extent and degree of staining inversely parallels tumor grade with decreasing staining with less differentiation
 - Argentaffin staining (e.g., Fontana-Masson) may be positive characterized by presence of intracytoplasmic black material.
 - In presence of glandular differentiation, intraluminal mucicarmine and diastase-resistant, PAS-positive material can be seen.
- Immunohistochemistry:
 - Cytokeratins positive:
 - AE1/AE3, CAM5.2 consistently strongly positive
 - CK7, CK20 may be positive
 - EMA, CEA positive
 - Synaptophysin, chromogranin, neuron-specific enolase, CD56, Leu-7 (CD57) positive
 - Serotonin and somatostatin may be positive.
 - Calcitonin, TTF1, S100 protein negative
 - p63 usually negative
- Electron microscopy:
 - Abundant neurosecretory granules (90 to 230 nm); cellular junctional complexes, intercellular, and intracellular lumina are present.

Differential Diagnosis

- Laryngeal paraganglioma:
 - Absent staining with epithelial markers:
 - Rare examples may be cytokeratin positive.
 - Presence of S100 protein (and GFAP) in peripheral situated sustentacular cells:
 - Feature not identified in neuroendocrine carcinomas
 - GATA3 immunoreactivity seen in paragangliomas but absent in (laryngeal) neuroendocrine carcinomas
- Atypical carcinoid (see below)

Treatment and Prognosis

- Conservative but complete surgical excision is preferred treatment.
- Neck dissection not indicated
- Indolent biologic behavior:
 - Generally carries an excellent prognosis after excision

- 5-year disease-specific survival (DSS) of 100% reported
- May metastasize in approximately one third of patients:
 - Metastasis occurs to liver, bone, lymph nodes, and skin.
 - Metastases may occur late in the disease course.

Atypical Carcinoid

(Figs. 16-63 through 16-67)

Synonym: Moderately differentiated neuroendocrine carcinoma (MDNEC)

Clinical

- Most common laryngeal neuroendocrine carcinoma
- Most patients have a history of heavy tobacco smoking use.

Fig. 16-63. Atypical carcinoid.

Laryngeal atypical carcinoid appearing as a large supraglottic-based mass with extension outside the larynx proper.

Fig. 16-64. Atypical carcinoid.

A, B, Laryngeal atypical carcinoid characterized by the presence of a submucosal neoplastic proliferation with organoid growth and fibrovascular stroma.

Fig. 16-65. Atypical carcinoid.

A through **D**, Laryngeal atypical carcinoid with organoid or cell nest, trabecular and solid growth patterns composed of cells with round to oval nuclei, dispersed to hyperchromatic nuclear chromatin, inconspicuous to small nucleoli and eosinophilic cytoplasm; variable but definite nuclear pleomorphism is present, and there is increased mitotic activity. The presence of nuclear pleomorphism and mitotic activity is greater than that seen in carcinoid tumor but not as prominent as in small cell and large cell neuroendocrine carcinomas. **E**, Perineural invasion (*arrow*) can be seen in atypical carcinoid representing another feature that would contrast to (typical) carcinoid tumor.

Fig. 16-66. Immunohistochemical staining of atypical carcinoid.

Immunoreactivity in laryngeal atypical carcinoid includes **(A)** cytokeratin (CAM5.2), **(B)** synaptophysin, **(C)** calcitonin, and **(D)** thyroid transcription factor 1. **E**, Ultrastructural findings include the presence of neurosecretory granules (lower right of illustration).

Fig. 16-67. Metastatic atypical carcinoid.

Metastasis from laryngeal atypical carcinoid tumor may include **(A)** subcutaneous metastasis and **(B)** cervical neck lymph node with almost complete replacement of the lymph node by metastatic tumor. In the presence of an unknown primary tumor, the histology and immunohistochemical staining of metastatic laryngeal atypical carcinoid will be similar to those of a metastatic medullary thyroid carcinoma, including immunoreactivity for cytokeratins, neuroendocrine markers, calcitonin, and thyroid transcription factor 1. In contrast to medullary thyroid carcinoma, serum calcitonin levels would not be expected to be elevated in patients with laryngeal atypical carcinoid tumor.

- Carcinoid syndrome rarely occurs in association with atypical carcinoid tumor.

Pathology

Gross

- Submucosal nodular or polypoid mass with a tan-white appearance varying in size from a few millimeters up to 4 cm in diameter.
- Surface ulceration may be present.

Histology

- Submucosal tumor arranged in organoid, trabecular, cribriform, or solid growth with a prominent fibrovascular stroma; infiltrative growth is present, including neurotropism and angioinvasion.
- Neoplastic cells show mild to marked cellular pleomorphism with round to oval nuclei, vesicular to hyperchromatic chromatin, and eosinophilic cytoplasm:
 - Nuclei can be centrally or eccentrically located.
 - Nucleoli may be prominent.
 - Nuclear chromatin described as “salt and pepper” in appearance with absence of nucleoli
 - Oncocytic cytoplasmic changes may be present.
- Mitoses, although uncommon, can be seen:
 - Never reach a level associated with large cell neuroendocrine carcinoma of 10 mitoses per 10 high-power fields (see below)
- Necrosis may be focally identified.
- Glands and squamous differentiation can be identified; neural-type rosettes rarely may be present:
 - May rarely occur in association with squamous cell carcinoma
 - In presence of squamous differentiation, a diagnosis of basaloid squamous cell carcinoma should be excluded.
- Surface ulceration may be prominent.
- Lymph-vascular and/or and perineural invasion may be present.
- Histochemistry:
 - Presence of epithelial mucin (diastase-resistant, PAS-positive, and occasionally mucicarmine positive), argyrophilia; rarely, argentaffin positive
- Immunohistochemistry:
 - Cytokeratins (96%), chromogranin (94%), synaptophysin (100%)
 - Other positive markers may include neuron-specific enolase, CD56, Leu-7 (CD57), neurofilament protein, epithelial membrane antigen, and carcinoembryonic antigen positive
 - Calcitonin is frequently positive (up to 80% of cases).
 - S100 protein, somatostatin, serotonin, adrenocorticotrophic hormone, gastrin, and glucagon may be positive.

- p63 variably positive and when present tends to be focal and weak
- TTF1 and melanoma-related markers are negative.
- Increased proliferation rates seen by Ki67 (MIB1) staining
- p53 overexpression
- p16 and HPV16 by PCR reported positive in a single case:
 - Whether there is any link and/or role of high-risk HPV in pathogenesis remains uncertain.
 - Whether there is any ameliorating effect of HPV on prognosis of LNEC remains uncertain.
- Electron microscopy:
 - Neurosecretory granules are commonly seen (70 to 420 nm); cellular junctional complexes, inter- and intracellular lumina are present.
- Radiotherapy and chemotherapy not considered beneficial as this tumor type is resistant to these therapies.
- Overall survival rates include:
 - 5-year survival rate of 48%
 - 10-year survival rate of 30%
- 5-year disease-specific survival (DSS) of 53%:
 - Patients treated with surgery had better DSS than those treated with radiotherapy.
 - Postoperative radiotherapy did not result in better DSS.
- Fully malignant tumor that often metastasizes to:
 - Cervical lymph nodes (43% of patients)
 - Lungs, bone, liver (44% of patients)
 - Skin and subcutaneous tissue (22% of patients)
- Prognosis is dependent on extent of disease at presentation:
 - When the tumor is confined to the larynx, 62% tumor-free over median of 3 years 9 months
 - Presence of metastatic disease (either at presentation or developing subsequently) is an ominous sign, with death at intervals ranging from 1 to 6 years.
- Size of primary tumor is prognostically important as tumors measuring greater than 1 cm have twice the mortality rate as tumors measuring less than 1 cm.
- Death results from metastatic disease.

Differential Diagnosis

- Carcinoid tumor
- Medullary thyroid carcinoma:
 - Differentiation of atypical carcinoid from a medullary thyroid carcinoma can be problematic in presence of cervical lymph node metastasis of unknown primary origin given overlapping histologic and immunohistochemical features including:
 - Organoid growth with cells showing features of neuroendocrine differentiation
 - Immunohistochemical reactivity for cytokeratins, synaptophysin, and calcitonin
 - Presence of a thyroid-based mass would support a diagnosis of medullary thyroid carcinoma, but in the absence of a thyroid mass, differentiation can be made on basis of increased serum calcitonin levels, which are almost invariably elevated in medullary thyroid carcinoma and almost always within normal limits in atypical carcinoid
- Basaloid squamous cell carcinoma
- Laryngeal malignant melanoma

Treatment and Prognosis

- Complete surgical excision is the preferred treatment:
 - Depending on site surgery may include partial or total laryngectomy
 - High incidence of cervical lymph node metastasis warrants neck dissection even in clinically N0 necks:
 - Nodal metastasis may be present at time of presentation or subsequently develop nodal metastasis.
 - Patients not undergoing surgical treatment of the neck reported to develop isolated regional recurrence in 30% of cases

Small Cell Undifferentiated Neuroendocrine Carcinoma (SCUNC) (Figs. 16-68 through 16-70)

Synonyms: Poorly differentiated neuroendocrine carcinoma (PDNEC); small cell carcinomas; “oat” cell carcinoma

Clinical

- Second most common laryngeal neuroendocrine carcinoma but represents less than 1% of all laryngeal malignant tumors
- Most patients have a history of heavy tobacco smoking use.
- A paraneoplastic syndrome occasionally may occur in association with SCUNC and may include:
 - Cushing syndrome
 - Eaton-Lambert syndrome
 - Schwartz-Bartter syndrome

Pathology

Gross

- Submucosal mass usually with surface ulceration

Fig. 16-68. Small cell undifferentiated neuroendocrine carcinoma of the larynx.

A, Submucosal hypercellular tumor with solid, trabecular, and lobular growth. **B,** Small round cell malignant infiltrate composed of hyperchromatic, round to oval to spindle-appearing nuclei with nuclear molding, inconspicuous to small nucleoli, and increased mitotic activity. **C** and **D,** Small round cell (undifferentiated) malignant cellular infiltrate with confluent foci of necrosis as well as individual cell necrosis with numerous mitotic figures present.

Histology

- Submucosal tumor may be arranged in solid nests, sheets, or ribbons with absence of a fibrovascular stromal component.
- Hypercellular with hyperchromatic, pleomorphic, oval to spindle-shaped nuclei, increased nuclear-to-cytoplasmic ratio, nondescript cytoplasm, and indistinct cell borders:
 - Nuclear chromatin may vary from dispersed coarse-appearing described as “salt and pepper” to hyperchromatic.
 - Absence of nucleoli
 - “Crush” artifact is frequently present.
 - Confluent foci of necrosis and individual cell necrosis seen
 - Abundant mitoses, including atypical forms
 - Nuclear molding may be identified.
- Glands and squamous differentiation rarely present
- Neural-type rosettes rarely may be present.
- May occur in association with squamous cell carcinoma and less often with an adenocarcinoma:
 - These tumors are referred to as combined or composite tumors.
- Surface ulceration often present
- Lymph-vascular and/or and perineural invasion may be present.
- In combined or composite carcinoma there is an admixture of small cell neuroendocrine carcinoma and either a squamous cell carcinoma or adenocarcinoma:
 - Squamous carcinoma component includes carcinoma in situ and/or invasive squamous cell carcinoma.
 - In presence of squamous differentiation a diagnosis of basaloid squamous cell carcinoma should be excluded.
- Histochemistry:
 - Argyrophilia rarely present
 - Argentaffin stains usually negative

Fig. 16-69. SCUNC.

In addition to the usual morphology, other findings that may be seen in (laryngeal) small cell undifferentiated neuroendocrine carcinoma may include **(A)** prominent spindle-shaped nuclei and **(B)** presence of true (neural-type) rosettes.

- Staining for epithelial mucin (e.g., mucicarmine, PAS with diastase) may be present.
- Immunohistochemistry:
 - Cytokeratins (AE1/AE3, CAM5.2, others) positive:
 - Often characterized by paranuclear (punctate) staining pattern
 - CK7 and CK20 may be positive.
 - High molecular weight cytokeratins, including CK 5/6 and CK903 (34 β E12), typically negative but may be positive and when positive is focal
 - Neuroendocrine markers, including synaptophysin, CD56, neuron-specific enolase positive:
 - Chromogranin may be positive but only focally and may be negative.
 - CD57, neurofilament protein may be positive.
 - TTF1 may be positive.
 - Variability of p63 staining that may include focal to diffuse reactivity
 - Epithelial membrane antigen and carcinoembryonic antigen positive

Fig. 16-70. IHC in SCUNC.

Immunoreactivity that can be seen in small cell undifferentiated neuroendocrine carcinoma may include **(A)** cytochrome c oxidase (CytOx) with paranuclear dot-like staining; **(B)** synaptophysin.

- Calcitonin rarely is positive.
- Melanocytic, hematolymphoid, and mesenchymal (e.g., myogenic) markers negative
- In association with laryngeal SCUNC, p16, and HPV16 by PCR reported positive in a single case:
 - Whether there is any link and/or role of high-risk HPV in pathogenesis remains uncertain.
 - Whether there is any ameliorating effect of HPV on prognosis of LNEC remains uncertain.
- In association with oropharyngeal SCUNC, p16, and HPV DNA identified in majority of cases (see Section 3, Pharynx)
- Electron microscopy:
 - Scanty neurosecretory granules (50 to 200 nm); cellular junctional complexes, inter- and intracellular lumina are usually absent.

Differential Diagnosis

- Poorly differentiated squamous cell carcinoma:
 - Cytokeratin staining present but lacks punctate paranuclear staining seen in SCUNC
 - High molecular weight keratins including CK5/6 and CK903 (34 β E12) diffusely and strongly positive
 - p63 diffuse and strong reactivity
- Basaloid squamous cell carcinoma (see Table 16-4)
 - In larynx also predilects to supraglottis
 - Cytokeratin staining present but lacks punctate paranuclear staining seen in SCUNC
 - High molecular weight keratins including CK5/6 and CK903 (34 β E12) diffusely and strongly positive:
 - SCUNC lacks such diffuse and strong staining.
 - p63 diffuse and strong reactivity:
 - SCUNC lacks such diffuse and strong staining.
 - Absence of TTF1 contrasts with the positive immunohistochemical staining pattern for this marker in SCUNC.
- Adenoid cystic carcinoma (see Table 16-4)
- Adenosquamous carcinoma
- Paraganglioma
- Extramedullary plasmacytoma
- Metastatic small cell carcinoma of lung origin
- Primary laryngeal malignant melanoma and metastatic melanoma to the larynx

Treatment and Prognosis

- Preferred treatment is nonsurgical and includes chemoradiotherapy:
 - Many patients have disseminated disease at presentation, obviating the option of laryngectomy and neck dissection.
- Highly lethal tumors with aggressive malignant behavior:
 - Metastases are commonly seen to:
 - Regional lymph nodes in a majority of patients (60% to 90%)
 - Liver, lung, bone, and brain
- Prognosis is poor:
 - 2-year survival of 16%
 - 5-year survival of 5%
- 5-year disease-specific survival (DSS) of 19%
- Treatment for combined or composite carcinoma is same as for small cell undifferentiated neuroendocrine carcinoma without combined squamous cell carcinoma or adenocarcinoma.
- In contrast to the relatively favorable prognosis associated with HPV-associated squamous cell carcinomas of head and neck, findings of HPV-associated neuroendocrine carcinomas suggest aggressive behavior despite association with HPV.

Large Cell Neuroendocrine Carcinoma (LCNEC) (Figs. 16-71 and 16-72)

Definition: Neoplasm fulfilling proposed diagnostic criteria for pulmonary large cell neuroendocrine carcinoma, albeit in the larynx.

- Relatively recently defined subtype of NEC likely previously subsumed within the spectrum of atypical carcinoids but distinct from atypical carcinoid histologically and associated with poorer outcome
- Within the classification of neuroendocrine carcinomas, LCNEC belongs with small cell neuroendocrine carcinoma within the spectrum of poorly differentiated neuroendocrine carcinomas.

Clinical

- To date, fewer than 50 cases reported in the literature
- Laryngeal LCNEC:
 - More common in men than women
 - Occur over a wide age range; average age of 59 years
- Symptoms may include hoarseness, dysphagia, odynophagia, otalgia, weight loss, heartburn (pyrosis), and/or cervical adenopathy
- Sites of origin include larynx > oropharynx, sinusal, hypopharynx, nasopharynx:
 - In larynx predilect to supraglottic region
 - With defined criteria (see below) likely will be recognized in other head and neck sites
- Most patients have history of heavy tobacco smoking.
- No known association with HPV

Pathology

Histology (Table 16-8)

- Criteria for diagnosis include:
 - Presence of features of neuroendocrine differentiation including organoid nesting, trabecular growth, rosettes, and peripheral palisading
 - Presence of enlarged tumor cells with vesicular chromatin, small to prominent nucleoli, and moderate to abundant cytoplasm
 - Increased mitotic activity (greater than 10 mitoses per 10 high-power fields [2 mm²])
 - Confirmation of neuroendocrine differentiation using immunohistochemical staining for chromogranin, synaptophysin, neuron-specific enolase, and/or neural cell adhesion molecule (CD56)
 - All four of requisite criteria must be present to make a diagnosis of LCNEC.
- Immunohistochemistry
 - Reactivity for cytokeratin (AE1/AE3):
 - CK5/6 and 34 β E12 typically negative

Fig. 16-71. Laryngeal large cell neuroendocrine carcinoma.

The histologic findings seen in large cell neuroendocrine carcinoma of the larynx include (**A** and **B**) presence of features of neuroendocrine differentiation including organoid, cell nest, and/or trabecular growth. **C** and **D**, Presence of large lesional cells vesicular chromatin, identifiable nucleoli, and moderate to abundant cytoplasm as well as increased mitotic activity (overall greater than 10 mitoses per 10 high-power fields [2 mm²]). (Unstained slides provided by James Lewis Jr., MD.)

- Neuroendocrine markers (chromogranin, synaptophysin, and CD56) positive
- Calcitonin and thyroid transcription factor 1 typically negative
- Increased proliferation rates by Ki67 (MIB1) staining typically >20%
- p53 overexpression

Differential Diagnosis

- Atypical carcinoid (AC):
 - Lacks increased mitotic rate, Ki67 labeling indices, p53 immunoreactivity, and low 5-year survival rates associated with LCNEC:
 - Mitotic activity in AC less than 10 mitoses per 10 high-power fields
 - Ki67 indices in AC less than 20% (more on order of less than 10%)

- Absence of p53 overexpression
- 83% 5-year survival as compared with <21% 5-year survival in LCNEC

Treatment and Prognosis

- Preferred treatment is nonsurgical and includes chemoradiotherapy:
 - Many patients have disseminated disease at presentation, obviating the option of laryngectomy and neck dissection.
- Commonly present with advanced stage (stages III and IV):
 - May be metastatic to cervical lymph nodes at presentation
 - May be metastatic to distant sites at presentation (e.g., liver)
- 5-year disease-specific survival (DSS) of 15% to 21%

Fig. 16-72. IHC reactivity in laryngeal large cell neuroendocrine carcinoma.

Confirmation of neuroendocrine differentiation by immunohistochemical staining includes reactivity for **(A)** synaptophysin, **(B)** chromogranin (focal positive cells), and **(C)** CD56. **D**, In addition, cytokeratin (CAM5.2) with paranuclear dot-like staining is also present. (Unstained slides provided by James Lewis Jr., MD.)

LARYNGEAL MUCOSAL MALIGNANT MELANOMA

See illustrations under mucosal malignant melanoma of the sinonasal tract.

Definition: Neural crest-derived neoplasms originating from melanocytes and demonstrating melanocytic differentiation.

Clinical

- Approximately 15% to 20% of all malignant melanomas arise in head and neck sites, and of these more than 80% are of cutaneous origin; of the approximate remaining 20%, the majority are of ocular origin.
- Mucosal malignant melanomas (MMM) of the upper aerodigestive tract represent from 0.5% to 3% of melanomas of all sites:

- In the upper aerodigestive tract, the most common site of occurrence is the sinonasal tract.
- Primary laryngeal mucosal malignant melanomas (PLMMM) are rare with fewer than 60 cases reported in the world literature.
- Metastasis to mucosal site must be excluded prior to diagnosing primary mucosal malignant melanoma.

Primary Laryngeal Mucosal Malignant Melanoma (PLMMM)

- Much more common in men than in women, with more than 80% of cases occurring in men; occur over a wide age range from 35 to 86 years of age, with an average age of 58 years, and are most frequent in the sixth and seventh decades of life
- Most cases occur in Caucasians but blacks are also affected.

TABLE 16-8 Pathologic Criteria for Large Cell Neuroendocrine Carcinoma of the Larynx

Requisite Criteria*	Other Typical Features
Tumor cells with moderate to abundant cytoplasm	Nuclei with prominent nucleoli
Features of neuroendocrine differentiation (organoid nesting, trabecular growth, rosettes, and peripheral palisading)	Cellular pleomorphism
Mitotic activity > 10/10 hpf (2 mm ²)	Large areas of necrosis
Confirmation of neuroendocrine differentiation using immunohistochemical staining for chromogranin-A, synaptophysin, neuron-specific enolase, and/or neural cell adhesion molecule (CD56)	

*All four requisite criteria must be present.

From Lewis J, Spence DC, Chiosea S, et al: Large cell neuroendocrine carcinoma of the larynx: definition of an entity, *Head Neck Pathol* 4:198-207, 2010.

- Majority (more than 60% of case in which the site is documented) occur in the supraglottic larynx, including the epiglottis, arytenoids, aryepiglottic folds, ventricle, false vocal cord, and piriform fossa
 - Other less common sites of occurrence include the glottic region along the true vocal cord and the posterior commissure.
 - To date, no documented reports involve the subglottic region.
- Clinical presentation includes hoarseness, dysphagia, sore throat, intermittent hemoptysis, neck or jaw pain, and a cervical neck mass:
 - Symptoms generally occur over short periods of time, ranging from 3 to 6 months.
- Multicentric (synchronous, metachronous) MMM of other upper aerodigestive tract sites are not typically present.
- No known etiologic factors:
 - Occur in patients who smoke tobacco and/or drink alcohol but no definitive link to these risk factors
 - Melanosis, intralaryngeal nevi, and lentigo of the larynx have been reported; given the development of cutaneous malignant melanomas from congenital melanocytic nevi and intradermal nevi, it is possible to suggest that PLMMM may arise from malignant transformation of intralaryngeal melanocytes or melanocytic lesions.

Pathology

Gross

- Nodular, mulberry-like, sessile, polypoid, exophytic, or pedunculated lesions with equally variable color,

including black, brown, red-pink, tan-gray, and white

- Range in size from 3 to 4 mm up to 8.0 cm in greatest dimension

Histology

- Infiltrative tumors composed of epithelioid cells, spindle-shaped cells, or an admixture of cell types
- Epithelioid MMM:
 - Growth patterns vary and include solid, organoid, nested, trabecular, alveolar, or any combination of these patterns.
 - Cells are round to oval, tend to be markedly pleomorphic with increased nuclear-cytoplasmic ratio, vesicular to hyperchromatic nuclei, prominent eosinophilic nucleoli, and eosinophilic to clear-appearing cytoplasm.
 - Nuclear pseudoinclusions and nuclear molding are present.
 - Epithelioid cells may have plasmacytoid features with eccentric located nuclei and an eosinophilic cytoplasm; a paranuclear clear zone is not seen.
- Spindle MMM
 - Growth patterns include storiform or fascicular.
 - Cells are oblong to cigar-shaped, markedly pleomorphic, with large vesicular to hyperchromatic nuclei, absent to prominent nucleoli, and scant eosinophilic cytoplasm.
 - Spindle cells may have an associated myxoid stroma.
 - Tumors with mixed epithelioid and spindle cells can be seen.
- For epithelioid and spindle cell MMM, necrosis and increased mitoses with atypical mitotic figures are common findings; uncommon features include neoplastic giant cells and glandular and squamous differentiation.
- Intracytoplasmic melanin may be present but often melanin pigment is not readily identifiable:
 - May demonstrate presence of heavy melanin deposition but approximately one third of cases have focal, weak pigmentation or are nonpigmented.
 - When present, intracytoplasmic melanin is usually found in scattered cells.
- In the presence of an intact surface epithelium, continuity of the tumor with the surface epithelium (i.e., junctional or pagetoid changes) can be identified; however, even in the presence of intact surface epithelium, junctional changes may not be seen:
 - Given the fact that normal melanocytes may localize to the submucosal compartment within minor salivary glands or within the stroma, junctional change is not required to render a diagnosis of MMM.

- **Histochemistry:**
 - Argentaffin (Fontana stain) and argyrophilic (Churukian-Schenk stain) positive
 - Intracytoplasmic diastase-sensitive, periodic acid Schiff material indicative of glycogen can be seen.
 - Mucin is absent.
- **Immunohistochemistry:**
 - S100 protein positive
 - Melanocytic markers including HMB-45, melan-A, tyrosinase, MiTF, Sox10 positive
 - Vimentin positive
 - Epithelial, neuroendocrine, and hematolymphoid markers are negative.
 - Desmin, actins, myogenin, and myoglobin are negative.
- **Electron microscopy:**
 - The ultrastructural findings of malignant melanoma include the presence of organelles characteristic of melanocytic differentiation; the latter include melanosomes and premelanosomes, both of which are membrane-limited vesicles with distinctive internal structure varying from parallel lamellae to helical to zigzag structures with a periodicity of 8 to 10 nm.

Differential Diagnosis

- Squamous cell carcinoma
- Spindle cell squamous carcinoma
- Neuroendocrine carcinoma
- Inflammatory myofibroblastic tumor

Treatment and Prognosis

- Radical surgical excision is the preferred treatment.
- Adjuvant radiotherapy and chemotherapy of questionable value
- Poor prognosis:
 - 5-year survival rate of less than 20%
- Approximately 80% of patients with PLMMM have metastatic disease to the regional lymph nodes as well as to distant viscera (e.g., brain, lungs, bone).
- Pathologic criteria that are used to predict the biologic behavior in association with cutaneous melanomas, including the depth of invasion, age and gender of the patient, and cytomorphology, generally do not apply for PLMMM; in addition:
 - In some studies prognostic significance has not been found for tumor thickness, level of invasion, ulceration, mitotic index, or nerve/nerve sheath involvement for MMM.
 - Other studies have shown significant adverse prognostic factors for disease-specific survival for MMM of the head and neck linked to advanced clinical stage at presentation, tumor thickness of greater than 5 mm, histologically proven

lymph-vascular space invasion, and metastatic disease (regional and distant).

NONEPITHELIAL MALIGNANT NEOPLASMS OF THE LARYNX

- Nonepithelial malignant tumors of the larynx and trachea are rare and include sarcomas and hematolymphoid malignancies.
- In the larynx, most common sarcoma is chondrosarcoma (see below).
- Other sarcomas that may arise in the larynx and trachea include:
 - Synovial sarcoma
 - Liposarcoma (see below)
 - Rhabdomyosarcoma
 - Leiomyosarcoma
 - Angiosarcoma
 - Malignant peripheral nerve sheath tumor
 - Undifferentiated pleomorphic sarcoma
 - Fibrosarcoma
 - Osteosarcoma
 - Others
- Malignant lymphomas of the larynx and trachea are rare and include:
 - Non-Hodgkin lymphomas:
 - Most are B-cell lymphomas including diffuse large B-cell lymphoma and extranodal marginal B-cell lymphoma of the MALT type
 - Rarely peripheral T-cell lymphomas and NK/T-cell lymphoma of nasal-type
 - Plasmacytoma
 - Hodgkin lymphoma

Chondrosarcoma

(Figs. 16-73 through 16-76)

Definition: Malignant tumor of cartilage.

Clinical

- In general, rare neoplasm in all head and neck sites
- Represents most common nonepithelial malignancy of the larynx, accounting for 75% of all sarcomas of this region, but only represents approximately 1% of all laryngeal tumors:
 - Other sites of involvement include mandible, maxilla, maxillofacial skeleton (nose and paranasal sinuses), nasopharynx.
 - See Section 2, Oral Cavity, for discussion of gnathic chondrosarcomas including mesenchymal chondrosarcoma.
- More common in men than women; may occur over a wide age range but most often occur in the sixth through ninth decades of life

Fig. 16-73. Chondrosarcoma of the larynx.

A, Endoscopic view shows a large bulge in the region of the cricoid (*C*). Note that the mucosa is intact and is not ulcerated. **B**, T1-weighted image shows the large submucosal mass (*arrowhead*). Note its position in the posterior larynx. There is no abnormality in the paraglottic fat (*arrow*). **C**, Slightly lower than **B**. Axial image through the cricoid cartilage shows a well-defined defect (*arrowhead*). The sharp margin would be unusual in invasion by squamous carcinoma. This indicates the origin within the cricoid cartilage. **D**, T2-weighted axial image shows the tumor (*T*) to have the high signal characteristic of chondrosarcoma. **E**, Axial CT shows a large mass with small punctate calcifications (*arrowheads*). This suggests the chondroid nature of the lesion. **F**, Axial scan through the cricoid shows the sharp margin of the lesion (*arrowheads*) as it abuts the normal cartilage. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Figure 31-87, p 1978.)

Fig. 16-74. Laryngeal chondrosarcoma.

Laryngeal chondrosarcoma appearing as smooth, lobulated, glistening mass arising from the cricoid cartilage.

- Most common site in the larynx is anterior surface of the posterior lamina of the cricoid cartilage:
 - Less often arises in the thyroid cartilage and arytenoids:
 - Predominantly occur in ossified hyaline cartilages
 - Nearly all cases arise from hyaline rather than elastic cartilage.
- Clinical presentation includes hoarseness, airway obstruction, and dyspnea.
 - Vocal cord paralysis may be present.
 - Involvement of the thyroid lamina may result in the presence of a neck mass.
 - Typically are submucosal appearing endoscopically as a subglottic swelling with overlying intact mucosa
- Radiology:
 - CT scan: circumscribed, hypodense mass with stippled to coarse calcifications resulting in expansion of the affected cartilage
 - MRI: delineates the extent of invasiveness and/or tumor boundaries
- No definitive cause and no link to pre-existing chondroma.

Pathology

Gross

- Bulky tumors that distort site of origin
- On cut section these tumors are solid with a smooth and lobulated appearance, are firm to hard consistency, are gray to white, and often measure greater than 2 cm in diameter.
- Degenerative changes may result in cyst formation, soft areas, and myxoid or gelatinous appearance.
- Fleshy appearance may indicate foci of dedifferentiation.

Histology

- Graded as low-grade or high-grade lesions based on the degree of cellularity, pleomorphism, multinucleated cells, and mitoses:
 - Most laryngeal chondrosarcomas are histologically low grade.
- At low magnification appear lobulated with irregular borders:
 - Invasive growth into adjacent structures can be seen.
- Majority are histologically low-grade that in comparison with chondromas show:
 - Increased cellularity
 - Nuclear hyperchromasia
 - Nuclear pleomorphism
 - Binucleate or multinucleate cells
 - Mitoses are uncommon and necrosis is typically absent.
- High-grade chondrosarcomas are less common:
 - Retaining overall lobular configuration although may only be focally identified
 - Histologically readily apparent as malignant based on the presence of hypercellularity, marked nuclear pleomorphism with bizarre cells, presence of prominent nucleoli, increased mitotic activity, and necrosis.
- In all histologic grades, ossification and/or calcification of hyaline cartilage may be present.
- Can be diagnosed on biopsy but must adhere to strict histologic criteria and clinical/radiologic correlation recommended
- Other histologic subtypes may include clear cell chondrosarcoma and dedifferentiated chondrosarcoma:
 - Clear cell chondrosarcoma:
 - Characterized by chondrocytes with clear cytoplasm and distinct cell membranes

Fig. 16-75. Low-grade laryngeal chondrosarcoma.

Laryngeal chondrosarcoma, low-grade (**A**) lobulated cartilaginous lesion showing increased cellularity; (**B**) occurrence of chondrosarcoma in hyaline cartilage with associated ossification and calcification (*arrows*) is a frequent finding; note the increased cellularity; (**C** and **D**) varying degree of increased cellularity may be present but the presence of binucleate chondrocytes (*arrows*) and nuclear pleomorphism and hyperchromasia (*arrowheads*) is a feature of low-grade chondrosarcoma. These overall findings contrast with those of chondroma, which generally lacks increased cellularity and atypical chondrocytes, but in any given case differentiating low-grade chondrosarcoma from chondroma can be extremely difficult. Lesional cells are immunoreactive for (**E**) S100 protein and

Continued

Fig. 16-75, cont'd

(F) podoplanin (D2-40).

Fig. 16-76. Laryngeal chondrosarcoma, high grade.

Left, Markedly cellular chondroid neoplasm. *Right*, the tumor is composed of pleomorphic cells with hyperchromatic, pleomorphic nuclei, prominent nucleoli, multinucleated cells, and mitoses.

- Dedifferentiated chondrosarcoma:
 - Characterized by the presence of an admixture of differentiated chondrosarcoma with high-grade, noncartilaginous sarcoma
- Immunohistochemistry (all types):
 - Vimentin and S100 protein positive
 - Podoplanin (D2-40) positive

Differential Diagnosis

- Chondroma:
 - May be extremely difficult to differentiate from low-grade chondrosarcoma

- Typically, chondromas are small, measuring less than 1 to 2 cm
- Histologically are characterized by the presence of scattered chondrocytes without nuclear atypia, hyperchromasia, binucleate, or multinucleate cells or mitoses.
- S100 protein and podoplanin (D2-40) positive
- Any purportedly recurrent chondroma likely represents a chondrosarcoma.
- Chondromatous metaplasia/hamartoma (chondro-metaplasia):
 - May present as a nodular mass of the larynx associated with progressive dysphonia, dyspnea, and dysphagia
 - History of laryngeal trauma
 - CT scan shows a rounded and circumscribed mass without infiltration of the surrounding tissues.
 - Histologically characterized by the nodular fibro-elastic cartilaginous tissue surrounded by a thin rim of fibrous tissue; rare hypercellular areas and occasional binucleated cells with slight hyperchromasia and irregular nuclear profiles may be seen but mitotic activity was absent
 - History of laryngeal trauma with the subsequent progressive onset of clinical symptoms helps to distinguish the chondrometaplastic nodule from true laryngeal cartilaginous tumor (e.g., chondroma and chondrosarcoma).
- Chordoma

Treatment and Prognosis

- For laryngeal chondrosarcoma treatment includes wide local (conservation) excision:
 - Conservative (organ sparing) surgery if feasible is recommended:
 - Endoscopic resection can be used for managing selected newly diagnosed cases of cricoid chondrosarcoma.
 - Organ preservation surgery represents a treatment option.
 - Total laryngectomy recommended in presence of high-grade histology, in presence of extensive cricoid involvement, and/or when conservative surgery is not possible
- Radiotherapy and chemotherapy not demonstrated to be effective therapeutic modalities
- In general, cure is achieved following complete excision of the tumor
 - Local recurrence occurs in approximately 25% of cases and can be managed by additional (definitive) surgery.
 - Recurrence is associated with incomplete excision and may occur years after initial diagnosis:
 - Long-term follow-up advised

- Distant metastases are uncommon but can occur (lungs).
 - Presence of higher-grade morphology and/or dedifferentiation more likely to be associated with metastasis
- 1-year, 5-year, and 10-year disease-specific survival reported as 96.5%, 88.6%, and 84.8%, respectively

Liposarcoma (Figs. 16-77 through 16-82)

Definition: Malignant tumor of adipocytes.

- Arise from primitive mesenchymal cells rather than mature adipose tissue, accounting for its presence in areas relatively devoid of fat (e.g., head and neck)

Clinical

- Represent 15% to 25% of all sarcomas
- Approximately 3% to 6% occur in head and neck:
 - In head and neck the most common sites of occurrence include the larynx and hypopharynx followed by the neck.
- For laryngeal and hypopharyngeal liposarcoma:
 - Tends to affect men more than women; occur over a wide age range but are most common in the sixth and seventh decades of life
- For neck liposarcomas:
 - No gender predilection; occur over a wide age range but usually occur in younger ages (approximately a decade younger) than non-head and neck liposarcomas
- Symptoms vary per site of involvement and size of the tumor:
 - Larynx: hoarseness, dysphonia, dysphagia, airway obstruction
 - Pharynx: dysphagia and airway obstruction
 - Neck: slowly growing painless mass
- Arise de novo; rarely originate from a pre-existing lipoma
- No known associated etiologic factors

Pathology

Gross

- Circumscribed and/or encapsulated, lobulated mass varying in appearance from yellow to tan-white and with a myxoid or gelatinous appearance
- Although liposarcomas can attain very large sizes, those identified in the head and neck rarely exceed 10 cm and are generally under 5 cm in greatest dimension.

Histology

- WHO classification includes:
 - Atypical lipomatous tumor/well-differentiated liposarcoma (ALT/WDL)
 - Dedifferentiated liposarcoma (DL)

- Myxoid/round cell liposarcoma
- Pleomorphic liposarcoma (PL)

Atypical Lipomatous Tumor/Well-Differentiated Liposarcoma (ALT/WDS)

- Most common morphologic type (30% to 40%) in late adult life
 - Most common morphologic type in relationship to upper aerodigestive tract liposarcomas
- Often diagnosed as lipoma due to its bland histology and only following one or more recurrences is a diagnosis of liposarcoma rendered.
- Histologically resembles a lipoma except for:
 - Greater variation in the size and shape of the adipocytes
 - Presence of scattered lipoblasts:
 - Absence of lipoblasts does not preclude a diagnosis of well-differentiated liposarcoma.
 - Absence of encapsulation
- Term atypical lipoma or atypical lipomatous tumor has been used for superficial (cutaneous or subcutaneous) lipogenic tumors with histologic appearance of well-differentiated liposarcomas that have a tendency to recur.
 - Use of this terminology should be viewed with caution in those well-differentiated liposarcomas occurring in more vital areas (deep neck, nasopharynx, sinonasal cavity, larynx, and hypopharynx) where inadequate excision and subsequent recurrence may result in increased morbidity and mortality.
 - Use of well-differentiated liposarcoma rather than atypical lipoma should convey to the surgeon that the neoplasm requires complete resection in as conservative a manner as to ensure tumor-free margins and not just simple excision.

Dedifferentiated Liposarcoma (DL)

- Histologic progression of ALT/WDL to a higher-grade, less well-differentiated neoplasm in:
 - Primary (de novo) neoplasm (90%)
 - Recurrent neoplasm (10%)
- High-grade component usually is nonlipogenic and only rarely is lipogenic.
- Accounts for 18% of all liposarcomas
- Most common site of occurrence is retroperitoneum >>> extremities
- Less than 20% occur in H&N (and other) sites
- Histology:
 - In approximately 90% dedifferentiated component has appearance of high-grade fibrosarcoma or undifferentiated pleomorphic sarcoma
 - Display range of subtypes including:
 - Most common: storiform-pleomorphic and myxoid forms

Fig. 16-77. Laryngeal liposarcoma.

A, Laryngeal liposarcoma appearing as a circumscribed polypoid, pedunculated mass. **B**, Resected hypopharyngeal liposarcoma with characteristic yellow appearance. **C** and **D**, This patient had a large hypopharyngeal-based mass that he was capable of “bringing up” at will; the tumor was excised via a lateral pharyngotomy approach.

Fig. 16-78. Laryngeal well-differentiated liposarcoma.

Laryngeal atypical lipomatous neoplasm/well-differentiated (lipoma-like) liposarcoma. **A**, Submucosal (surface squamous epithelium in lower left) adipose tissue proliferation composed of nests of fat cells separated by fibrous septa.

B, Adipocytes show variation in size and shape. **C** and **D**, Multivacuolated lipoblasts. Immunohistochemical staining assists in the diagnosis with reactivity for **(E)** MDM2 and **(F)** CDK4. These markers are absent in lipomas.

Fig. 16-79. Dedifferentiated liposarcoma.

A, Cervical neck dedifferentiated liposarcoma showing transition or interface between atypical lipomatous tumor/well-differentiated liposarcoma (*bottom half*) and dedifferentiated zone (*top half*). **B**, Area showing appearance of fibrosarcoma. **C** and **D**, Areas resembling undifferentiated pleomorphic sarcoma. The presence of immunoreactivity for **(E)** MDM2 and **(F)** CDK4 supports a diagnosis of dedifferentiated liposarcoma and allows for differentiation from other sarcomas (e.g., fibrosarcoma, undifferentiated pleomorphic sarcoma).

Fig. 16-80. Laryngeal myxoid and round cell liposarcoma.

Cellular myxoid lesion with plexiform capillary pattern plexiform vascularity with a delicate arborizing (capillary-like) pattern and lipoblasts in varying stages of development including signet-ring appearance. Myxoid liposarcoma is typically negative for MDM2 and CDK4.

- Less common: giant cell and inflammatory forms
- In approximately 10% may resemble low-grade fibrosarcoma or fibromatosis

Myxoid Liposarcoma

- Continuum of lesions that include differentiated myxoid tumors with lipoblastic differentiation to poorly differentiated round cell tumors with inconspicuous lipoblastic differentiation; included in this category are lesions previously referred to as round cell liposarcoma.
- Represents one third to one half of all liposarcomas
- Occurs in younger age group than ALT/WDL and DL:
 - Peak incidence in fifth decade of life
- Most common in lower extremity (75% of cases):
 - Medial thigh > popliteal area
 - Less commonly occurs in retroperitoneum
 - Rare in head and neck
- Myxoid liposarcoma characterized by:
 - Lobular or nodular growth
 - Uniform round to oval mesenchymal (nonlipogenic-appearing) cells
 - Variable numbers of signet ring lipoblasts are present:
 - Usually readily identifiable
 - May be most prominent at periphery of nodules
 - Prominent myxoid stroma rich in glycosaminoglycans or hyaluronidase-sensitive acid
 - Mucopolysaccharides

Fig. 16-81. Laryngeal myxoid and round cell liposarcoma.

Laryngeal myxoid/round cell liposarcoma. **A** and **B**, Transition from myxoid area (*left*) to cellular area composed of round cells. **C** and **D**, Densely cellular proliferation solid sheets of primitive round cells with hyperchromatic nuclei, enlarged nucleoli, increased nuclear-to-cytoplasmic ratio, vacuolated-appearing cytoplasm, and increased mitotic activity (*arrows*). Myxoid/round cell liposarcomas are typically negative for MDM2 and CDK4.

- Delicate plexiform capillary vascular pattern present:
 - Represents an important diagnostic clue
 - Assists in differentiating from benign tumors (e.g., myxoma, others)
- Cellular component typically lacks nuclear pleomorphism, significant mitotic activity, or tumor giant cells.
- Extracellular mucin pools or lakes creating a lymphangioma-like appearance can be identified.

Fig. 16-82. Cervical neck pleomorphic liposarcoma.

A, Cellular tumor composed of spindle and multinucleated giant cells. **B**, *Left*, markedly pleomorphic cells with cytoplasmic vacuolization; *right*, extra- and intracellular eosinophilic hyaline globules. **C**, Multivacuolated lipoblast (arrow). Pleomorphic liposarcomas are typically negative for MDM2 and CDK4.

- Cartilaginous, osseous, leiomyomatous differentiation may occur; rarely, rhabdomyosarcomatous differentiation may be present.
- Round cell liposarcoma:
 - Represents poorly differentiated form of myxoid liposarcoma characterized by the presence of:
 - Densely cellular proliferation solid sheets of back-to-back primitive round cells with hyperchromatic nuclei, prominent nucleoli, increased nuclear-to-cytoplasmic ratio, and granular to vacuolated-appearing cytoplasm
 - Increased mitotic activity as well as necrosis and hemorrhage are present.
 - Sparse to absent intervening myxoid, fibrillar, or myxomucinous stroma
 - Plexiform capillary vascular pattern present but generally compressed by the cellular proliferation
 - Presence of transitional areas from myxoid to hypercellular round cell supports contention that myxoid and round cell liposarcomas represent a histological continuum of myxoid liposarcomas:
- Further support of this consideration is the presence of shared chromosomal aberrations (see below).

Pleomorphic Liposarcoma

- High-grade sarcoma composed of:
 - Variable numbers of pleomorphic lipoblasts characterized by spindle and giant cells with one or more enlarged hyperchromatic nuclei scalloped by cytoplasmic vacuoles
 - Cytoplasmic vacuoles contain lipid droplets.
 - Majority of tumors have fascicles of spindle-shaped cells and smaller, round cells admixed with multinucleated giant cells resembling such tumors as undifferentiated pleomorphic sarcoma, as well as the pleomorphic lipoblasts
 - Limited lipoblastic features may be present.
 - Prominent cytoplasmic eosinophilia may be present and in the presence of limited lipoblastic findings may suggest a diagnosis of rhabdomyosarcoma.

- Extra- and intracellular eosinophilic hyaline globules may be identified and likely represent lysosomal structures.
- Absence of areas of ALT/WDL or other line of differentiation
- Epithelioid variant:
 - Predominantly composed of solid, cohesive sheets and clusters of epithelioid cells with round to oval nuclei, prominent nucleoli, eosinophilic cytoplasm, and distinct cell borders
 - Focally, lipogenic differentiation in the form of pleomorphic lipoblasts is present.
 - Often associated with a higher mitotic rate than is seen in association with pleomorphic (nonepithelioid) liposarcoma.
- Tumor necrosis is present in all morphologic types of pleomorphic liposarcoma.

Mixed Type Liposarcoma

- Extremely rare, representing approximately 5% (or less) of all liposarcomas
- Primarily occur in retroperitoneum
- Histologically defined by the presence of combined:
 - Classic WDL associated with classic pleomorphic liposarcoma
 - ALT/WDL with myxoid/round cell and well-differentiated/dedifferentiated liposarcoma
 - Myxoid/round cell and pleomorphic liposarcoma
- Molecular testing has allowed for classification of some of these mixed-type liposarcomas within one of neoplasm within current WHO classification.

Spindle Cell Liposarcoma

- Considered to represent rare atypical/low-grade malignant lipogenic neoplasm regarded as a variant of atypical lipomatous tumor
- Tends to occur in subcutaneous tissue of the extremities, trunk, and head and neck region
- Histologically, variably cellular neoplasms composed of atypical lipogenic cells showing variations in size and shape, and spindled tumor cells with slightly enlarged, often hyperchromatic nuclei:
 - Multivacuolated lipoblasts may be present.
 - Focal myxoid stromal changes may be present.
- Immunohistochemically:
 - CD34 at least focally positive
 - Only scattered cells in limited cases may show nuclear expression of MDM2.
 - FISH analysis negative for MDM2/CDK4 amplification
- Based on clinicopathologic and molecular findings may represent atypical/low-grade counterpart of spindle cell lipoma rather than morphologic variant of ALT/WDL

General Histologic Considerations

- Lipoblasts:
 - Neoplastic cell recapitulates differentiation cascade of normal fat:
 - Hyperchromatic indented or scalloped nucleus
 - Lipid-rich droplets in cytoplasm
 - Appropriate histologic background
 - Importance overemphasized
 - Few present in ALT/WDL:
 - Pattern and cellular components more important
 - Simulators of lipoblasts:
 - Reactive changes (fat necrosis; atrophy; foreign body reaction)
 - Fixation artifact
 - Signet ring cells in other neoplasms
- Mitoses, necrosis, and hemorrhage can be identified in all histologic variants and generally correlate to the amount of cellular pleomorphism (mitoses are particularly prominent in the pleomorphic variant).
- Histochemistry:
 - Special stains are of little if any assistance in diagnosis.
- Immunohistochemistry:
 - Adipocytes and lipoblasts variable S100 protein immunoreactive
 - Vimentin positive
- Cytogenetics and immunohistochemistry:
 - ALT/WDL:
 - Characterized by giant marker and ring chromosomes:
 - Contain amplified sequences 12q13-15, site of several genes (MDM2, CDK4, others)
 - MDM2 (and HMGA2) consistently amplified
 - CDK4 co-amplified in approximately 90%
 - MDM2 and CDK4
 - IHC:
 - ◻ MDM2 and CDK4 detected in majority of ALT/WDL: (nuclear staining) is a reasonable first tool in diagnosis
 - FISH:
 - ◻ Highly sensitive and specific
 - ◻ Superior to immunohistochemistry
 - ◻ Small false-positive rate
 - Absent in lipomas
 - Small percentage of spindle cell/pleomorphic lipoma express MDM2 and CDK4
 - Recommendation for use:
 - ◻ Lipomatous tumors with equivocal cytologic atypia
 - ◻ Recurrent lipomas
 - ◻ Deep lipomas with atypia >15 cm
 - ◻ Retroperitoneal and intra-abdominal tumors without atypia

- Dedifferentiated liposarcoma:
 - Share similar findings as ALT/WDL although display more extensive chromosomal abnormalities
 - 12q13-15 amplifications more complex than in ALT/WDL
 - IHC:
 - MDM2 and CDK4 reactivity
- Myxoid and round cell liposarcoma:
 - Characterized by reciprocal t(12;16)(q13;p11) translocation:
 - Present in more than 90% of cases
 - Results in fusion of the *DDIT3* gene on chromosome 12 with *FUS* gene on chromosome 16:
 - Presence of *FUS/DDIT3* fusion sensitive and specific for myxoid liposarcoma
 - Chimeric *FUS-DDIT3* gene results in 3 fusion transcripts:
 - Type II identified in most myxoid/round cell liposarcomas
 - Staining for MDM2 and CDK4 typically negative
- Pleomorphic liposarcoma:
 - Various chromosomal gains and losses
 - Dysregulation of several tumor suppressor pathways common
 - No amplification of 12q14-15 region
 - Staining for MDM2 and CDK4 typically negative
- Recurrence is common:
 - Generally occurs within 3 years after the initial treatment
 - Usually same histology as the primary tumor but may “dedifferentiate” with a histologic appearance less differentiated and with a more aggressive biology than the primary tumor.
- Nodal metastasis rare and neck dissection generally not indicated
- Distant metastasis may occur and are more common with the higher-grade histologic variants:
 - Metastases occur to the lungs, bone, and liver.
- 5-year survival rate for all liposarcomas of the head and neck approximately 67%
- 5-year survival rates influenced by histologic type:
 - Well-differentiated:
 - 85% to 100% 5-year survival
 - Myxoid:
 - 71% to 95% 5-year survival
 - Round cell:
 - 12.5% to 55% 5-year survival
 - Pleomorphic:
 - 0 to 45% 5-year survival
- In addition to histologic type, other factors important in prognosis include:
 - Size of the tumor
 - Location of the tumor:
 - Laryngeal/hypopharyngeal and facial tumors have the best prognosis.
 - Mouth and pharynx have the worst prognosis.
- Controversy exists as to the issue of multicentric occurring liposarcomas vs. metastatic liposarcoma:
 - Presence of clonality in multifocal myxoid liposarcoma supportive of metastasis rather than multifocal tumor

Differential Diagnosis

- Lipoma
- Myxoma (intramuscular; nerve sheath)
- Other sarcomas:
 - Rhabdomyosarcoma
 - Undifferentiated pleomorphic sarcoma
 - Myxoid chondrosarcoma
 - PNET/Ewing sarcoma
- Chordoma
- Signet ring cell carcinoma or lymphoma
- Malignant melanoma

Treatment and Prognosis

- Wide local surgical excision is the preferred treatment to include tumor-free margins.
 - More aggressive surgical procedures may be indicated for the other histologic variants.
- Utility of radiotherapy remains controversial, but evidence supports the use of postoperative radiotherapy as an adjunct to surgery:
 - In cases in which the tumor cannot be completely resected
 - In cases in which surgical margins are close

SECONDARY TUMORS

- Metastatic tumors to the larynx and trachea are rare.
- Most common tumor types to metastasize to this region include malignant melanoma and various carcinomas including those originating from the kidney, breast, lung, prostate, gastrointestinal tract (e.g., colon, stomach); less frequently, metastasis may originate from the female genital tract, kidney, thyroid gland, and other sites.
- In the larynx, most common site of metastasis is supraglottis followed by the subglottis:
 - Supraglottis and less so the subglottis are richly vascularized as compared with the glottic

region, accounting for the greater incidence of metastasis to the supraglottic and subglottic larynx.

- Symptoms vary per site of involvement:
 - Larynx: hoarseness, dysphagia, and/or pain
 - Trachea: cough, dyspnea, stridor, and hemoptysis
- Metastasis usually localizes to the submucosa or to cartilage that has undergone ossification.

- Metastasis to the larynx and trachea often occurs in the setting of disseminated disease in terminal or near-terminal patients.

Intraoperative Consultation of Laryngeal Lesions

- Issues relative to intraoperative consultation of laryngeal mucosal margins are similar to those discussed for intraoperative consultation of oral cavity mucosal lesions. The reader is referred to Section 2 for more detailed discussion, including illustrations.
- This section is an overview of the overlapping issues with the intraoperative consultation of laryngeal mucosal lesions and those of the oral cavity previously discussed in Section 2, Oral Cavity.

INDICATIONS

- Indications for intraoperative consultation of mucosal lesions of the upper aerodigestive tract include:
 - Render a histologic diagnosis (e.g., carcinoma/dysplasia) when definitive therapeutic intervention is planned immediately:
 - In laryngeal tumors most frequent indication for use of frozen section is documentation of residual tumor status
 - Intraoperative consultation with the purpose of primary tumor diagnosis is less common and discouraged.
 - Assessment of the adequacy of resection (i.e., surgical resection margins)
 - Preliminary assessment of the nature of a planned procedure based on the extent and distribution of the neoplasm (e.g., subtotal versus total laryngectomy)
 - Adequacy for diagnostic purposes (e.g., lymphoma)
 - Determination for special handling (e.g., immunohistochemistry, flow cytometry, microbiologic cultures)
 - Determination of neurotropism, lymph-vascular space invasion (LVI), or soft tissue involvement that may necessitate a more extensive resection
 - If lymph nodes are excised, then a frozen section may be requested to exclude the presence of metastatic disease and the need for a neck dissection.

SURGEON'S EXPECTATIONS

- Establish diagnosis of carcinoma/dysplasia and differentiate it from look-alike lesions.
- Confirm presence or absence of lesional tissue at the margins of resection.
- When applicable, identify the presence of osseous involvement.
- When applicable, identify the presence of nodal metastasis.

SPECIMEN HANDLING AND ORIENTATION

- Evaluation of surgical margins of resection for the presence or absence of lesional tissue falls under the purview of the surgical pathologists; however, how the specimen is removed and the orientation of the specimen is the responsibility of the surgeon:
 - Particularly true for those cases in which the tumor is initially excised and the designated margins are separately removed, the tumor is removed in multiple parts or the specimen is a complex en bloc excision requiring proper orientation by the surgeon for those margins that are of critical concern.
- Once removed and properly oriented, the specimen becomes the responsibility of the surgical pathologist.
- There is no standard method by which surgeons remove tissue and thereby request intraoperative consultation of the surgical resection margins; some approaches include:
 - Excision of the entire lesion, designation of specific margins, and tissue selection by the pathologist for frozen section
 - Circumferential resection margins are submitted for frozen section regardless of the number of frozen sections that may be required to completely evaluate the circumferential margins.
 - A limited number of frozen sections (e.g., up to four: anterior, posterior, medial, and lateral) are submitted as determined by the pathologist.

NOTE: Anatomy of the head and neck is complex, and in any given resection the risk posed by removing the entire lesion and surrounding structures for intraoperative consultation includes:

- Loss of the three-dimensional orientation of the specimen
- Erroneous sampling of the areas of concern
- Submission of biopsies from areas of clinical concern following the main resection and these biopsies are entirely submitted for frozen section.

DEFINITION OF A “POSITIVE” MARGIN

- Specimens in which no tumor or dysplasia is present at the surgical margins of resection are considered as completely excised.
- “At the margin of resection” means the neoplastic cells are seen in contact with or lie within millimeters of the pigment that was painted along the margin prior to sectioning (i.e., tumor across or up to the resection margin):
 - In this situation, the specimen is considered incompletely excised, requiring a wider excision to be assured that all viable tumor cells have been adequately removed.
- Sole reliance of margins as assessed on the resected specimen should be discouraged and, when feasible, intraoperative evaluation of tissue surrounding the specimen should be made and have that regarded as the “true margin.”
- Histologic definition of what constitutes a “positive” margin should be uniformly accepted and applied:
 - Discrepancy in the literature as to what constitutes a positive or negative resection margin
 - Some authorities include only invasive carcinoma at the margin as positive, excluding carcinoma intraepithelial dysplasia/carcinoma in situ and gross residual disease.
 - Most pathologists would agree with the classification of positive margins as defined by:
 - Presence of lesional tissue within 0.5 mm of the surgical margin (so-called close margins) with the exception of laryngeal lesions
 - Significant dysplastic epithelium at the margin:
 - High-grade squamous intraepithelial dysplasia to include moderate dysplasia and severe dysplasia/carcinoma in situ at a margin of resection is considered a positive margin
 - Invasive carcinoma at the margin
- Although frozen section diagnosis of surgical margins is extremely accurate, it is not entirely reliable in eliminating positive margins in the final diagnostic report.

ADEQUACY OF RESECTION MARGINS

- Presence of lesional tissue within 5 mm of the inked surgical margin regardless of whether it is invasive carcinoma or carcinoma in situ/severe dysplasia places a patient at a nearly equal risk for local recurrence:
 - These margins are associated with approximately 80% incidence of recurrent disease.
 - Absence of positive margins does not guarantee local control of disease nor is it a reliable guide to the biologic behavior of a tumor.
 - Presence of positive margins increased the likelihood of local recurrence but does not affect survival because subsequent surgery and/or irradiation may control tumor recurrence in some of their patients.
- The question of how wide a tumor should be excised is the responsibility of the surgeon:
 - For some specimens such as the larynx, free margins up to 5 mm may be sufficient:
 - Laryngeal margins with margins of ≤ 2 mm have 5-year survival rate similar to patients with tumor at the resected margin.
 - Patients with resected larynges including margin clearance >2 mm have essentially similar outcomes as patients with wider margin clearance.
 - With a similar tumor at another extralaryngeal site, such as the oral cavity and pharynx (oropharynx, hypopharynx), wider margins (1.0 cm) are optimal.

Embryology, Anatomy, and Histology of the Salivary Glands

- Salivary gland system composed of exocrine glandular tissue that include major salivary glands and minor salivary glands:
 - Major salivary glands include:
 - Parotid gland
 - Submandibular (submaxillary) gland
 - Sublingual gland
 - Minor salivary (seromucous) glands include:
 - Small aggregations within the submucosa of the upper aerodigestive tract
- All salivary glands share basic structure but vary per site in their function, secretions, gross and microscopic features:
 - Major and intraoral minor salivary glands produce fluids that constitute oral saliva.
 - Minor salivary (seromucous) glands outside the oral cavity including sinonasal tract, pharynx, larynx, trachea, bronchi are morphologically and functionally similar to oral minor salivary glands but in contrast do not contribute to saliva

EMBRYOLOGY OF THE SALIVARY GLANDS

- All salivary glands develop as solid proliferations or buds from the epithelium of the stomodeum during the fifth and sixth weeks of gestation:
 - Stomodeal epithelium is part ectoderm and part endoderm.
- Parotid gland:
 - First to form in humans
 - Arise from the ectodermal lining of the stomodeum from which the ducts, lumina, and acini evolve
 - Capsule and connective tissue develop from the surrounding mesenchyme
- Submandibular gland:
 - Develops from buds of the endoderm in the floor of the stomodeum from which the ducts, lumina, and acini evolve
- Sublingual gland:
 - Appears later than the other glands
 - Develop from buds of the endoderm in the paralingual sulcus from which the ducts, lumina, and acini evolve

- Minor salivary glands (seromucous glands):
 - Develop later in gestational life (third month)
 - Endodermally derived

NOTE: Parotid gland is last of the salivary glands to be encapsulated resulting in either incorporation/entrapment of lymphoid tissue within the parotid or incorporation/entrapment of parotid ducts and acini within the periparotid lymph nodes epithelium. (See next chapter for discussion and illustrations.)

ANATOMIC BORDERS OF THE SALIVARY GLAND

- See [Fig. 18-1](#).
- Parotid gland
 - Largest gland (average weight of 25 g)
 - Encapsulated and pyramidal-shaped palpable between the ramus of the mandible and the mastoid process
 - Artificially divided into two lobes by the coursing of the facial nerve through the gland:
 - Superficial lobe (largest portion)
 - Deep lobe situated adjacent to the lateral pharyngeal space
 - Anterior border:
 - Overlies the superficial surface of the masseter muscle
 - Posterior border:
 - Overlaps the sternocleidomastoid muscle and wraps around the lower ear
 - Lateral or superficial border:
 - Skin and dermis of the face
 - Medial or deep border:
 - Buttressed by the styloid process and its associated muscles (styloglossus, stylohyoid, stylopharyngeal) and by the carotid sheath and its contents (internal carotid artery, internal jugular vein, cranial nerves IX, X, XII)
 - Superior border:
 - Zygomatic arch
 - Inferior border:
 - Sternocleidomastoid muscle (oblique anterior border)
- Parotid (Stensen) duct:
 - Approximately 4 to 7 mm long
 - Originates from the anterior portion of the parotid coursing forward over the masseter

Fig. 18-1. Salivary glands and related anatomy.

A, Left lateral drawing of the face with the body of the mandible resected to show the floor of mouth structures. The relationships of the parotid gland, submandibular gland, and sublingual gland are shown. **B**, Left oblique view drawing from above shows the relationships of the left parotid gland to the mandibular ramus, pterygoid muscles, carotid sheath, and pharyngeal wall. Note the course of the facial nerve artificially dividing the parotid gland into a superficial lobe (largest portion) and deep lobe (smallest portion).

**Fig. 18-1, cont'd**

C, Left lateral view of the floor of mouth as seen with a midline cut. The submandibular gland can be seen to extend around the back edge of the mylohyoid muscle. The multiple ducts of the sublingual gland can be seen draining into the lateral floor of the mouth. (**A**, Modified from www.netterimages.com. **B**, From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, p 2450, Fig. 40-1. **C**, Modified from Sobota Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

- muscle, enters the buccal fat pad piercing the buccinator muscle, and opens in the oral cavity opposite the second maxillary molar (parotid papilla)
- In approximately 20% of the population, accessory parotid tissue is found along the anterior portion of the gland and Stensen duct.
- Submandibular (submaxillary) gland
 - Each gland weighs from 10 to 15 g.
 - Encapsulated and walnut-shaped, located in the submandibular triangle, situated below the angle of the mandible
 - Divided into superficial and deep lobes; the latter can only be palpated in the floor of the mouth
 - Anterior border:
 - Anterior belly of the digastric muscle
 - Posterior border:
 - Stylomandibular ligament, which separates it from the lower part of the parotid
 - Lateral border:
 - In relation to the submandibular fossa on the inner surface of the body of the mandible
 - Medial border:
 - Bounded by several muscles (mylohyoid, styloglossus, hyoglossus, stylohyoid, and posterior belly of the digastric) and nerves (hypoglossal, glossopharyngeal, and lingual)
 - Superior border:
 - Inferior border of the body of the mandible
 - Inferior border:
 - Skin, platysma, and deep fascia
 - Submandibular (Wharton) duct:
 - Runs forward along the inner surface of the mandible, in parallel with the lingual nerve passes medial to the lower border of the sublingual gland, at which point the duct may receive the major sublingual duct (Bartholin) prior to opening in the oral cavity at the sublingual caruncle or papilla lateral to the frenulum

- Sublingual gland
 - Smallest of the major salivary glands, weighing between 2 and 4 g
 - Almond-shaped, located submucosally in the floor of the mouth
 - Anterior border:
 - Opposite sublingual gland
 - Posterior border:
 - Deep part of the submandibular gland
 - Lateral border:
 - Internal aspect of the body of the mandible
 - Medial border:
 - Genioglossus muscle
 - Superior border:
 - Mucosa of the floor of the mouth, which it raises to form the sublingual fold
 - Inferior border:
 - Mylohyoid muscle
 - Has several ducts connecting to the oral cavity:
 - Several ducts unite to form the common sublingual (Bartholin) duct, the largest duct, which merges with the submandibular duct prior to opening in the oral cavity lateral to the frenulum
 - Smaller ducts known as Rivinus ducts open into the oral cavity proper.
- Minor salivary (seromucous) glands
 - Located beneath the mucosal epithelium throughout the submucosa of entire upper aerodigestive tract:
 - Are unencapsulated arranged in lobules
 - In tongue and lips lie in close contact with structures around them, including:
 - Skeletal muscle
 - Nerves
 - Anterior hard palate and gingiva generally devoid of seromucous glands

INNERVATION OF THE SALIVARY GLANDS

- Parotid gland
 - Auriculotemporal branch of the IX cranial nerve traverses the parotid gland and provides its sensory and secretomotor functions:
 - Frey syndrome, or auriculomotor nerve syndrome: occurs after parotidectomy when misdirected regeneration of the secretomotor fibers with innervation of the cutaneous sweat glands results in facial sweating during eating
 - VII (facial) nerve passes through the deep and posterior aspects of the parotid gland prior to dividing into its branches to the face:
 - Any surgical procedure to remove portions of the parotid gland, unless it involves only the superficial part, carries the danger of damage

to the nerve; maintaining the integrity and function of the facial nerve in the face of a total parotidectomy is a difficult and delicate procedure.

- Submandibular and sublingual glands:
 - Facial nerve (VII) provides the sensory and secretomotor function of these glands via the chorda tympani accompanying the lingual nerve (a branch of the mandibular division of V nerve) passing through the submandibular ganglion.
- Blood supply and lymphatic drainage
 - Parotid gland:
 - Arterial supply is via branches of the external carotid artery and includes the posterior auricular, maxillary, superficial temporal, and transverse facial arteries.
 - Venous structures parallel those of the arteries and empty into the external jugular vein
 - Lymphatic drainage is to the superficial and deep cervical lymph nodes via the superficial parotid lymph nodes.
 - Submandibular and sublingual glands:
 - Arterial supply to the submandibular gland is via branches of the external carotid artery the facial and lingual arteries; arterial supply to the sublingual gland is by the sublingual and submental arteries branches of the lingual and facial arteries, respectively.
 - Venous structures parallel those of the arteries and empty into the external and internal jugular veins.
 - Lymphatic drains to the superficial and deep cervical lymph nodes via submandibular and sublingual lymph nodes.

HISTOLOGY OF THE SALIVARY GLANDS

- See [Figs. 18-2 through 18-5](#); [Tables 18-1 and 18-2](#).
- Common to all salivary glands is their arborizing epithelial ductal system with production of saliva from the specialized secretory cells in the distal segments and delivery of these secretions via the complex branching structures to the oral cavity:
 - Main secretory duct of the gland divides into progressively smaller striated ducts that, in turn, branch into smaller intercalated ducts, which terminate in the terminal secretory end structures.
- From distal to proximal the system includes:
 - Acini represent the terminal secretory cells and include serous and/or mucous cells, which produce the saliva:
 - Serous cells:
 - Triangular to pyramidal cells with a narrow apex toward the luminal aspect, round nuclei near the basal one third of the cell, and

Fig. 18-2. Schematic drawing of salivary duct system.

A, The drawing shows the major salivary gland ductal system. **B**, The ductal system is shown with cross-sections at the various ductal levels. (**A**, Modified from Batsakis JG: *Tumors of the head and neck: clinical and pathological considerations*, ed 2, Baltimore, 1979, Williams & Wilkins. **B**, From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, 2454, Fig. 40-7B.)

- abundant cytoplasm containing numerous basophilic zymogen granules situated at the apical portion
- Zymogen granules are diastase-resistant, periodic acid Schiff positive, and mucicarmine negative.

- Mucous cells:
 - Pyramidal cells with basally located, flattened nuclei and clear to faintly basophilic, finely granular-appearing cytoplasm
 - Mucicarmine, alcian blue, and diastase-resistant, periodic acid Schiff positive

Fig. 18-3. Histologic features of acinar cell types in various salivary glands.

A, The parotid gland is composed of serous acini characterized by triangular to pyramidal cells with a narrow apex toward the luminal aspect, round nuclei near the basal one third of the cell, and abundant cytoplasm containing numerous basophilic zymogen granules situated at the apical portion. **B**, Although considered to be wholly composed of serous acini, mucous cells (arrows) can be seen in parotid gland parenchyma. **C**, The submandibular (and sublingual) gland is composed of an admixture of mucous and serous acini; serous cells typically arranged as crescent-shaped caps (referred to as demilunes) along the periphery of the mucous acinar cells. **D** and **E**, Palatal minor salivary glands are situated in the submucosa with a lobular arrangement and are wholly composed of mucous acini-appearing pyramidal cells with basally located, flattened nuclei and clear to faintly basophilic, finely granular-appearing cytoplasm. **F** and **G**, Minor salivary glands (seromucous glands) are situated in the submucosa with a lobular arrangement and composed of an admixture of mucous and serous cells.

**Fig. 18-3, cont'd**

H, Lingual and labial minor salivary glands can be seen in close contact with structures, around them including skeletal muscle and nerves, the latter including ganglion cells.

**Fig. 18-4. Histology of salivary gland ducts.**

A, Intercalated ducts are lined by low cuboidal cells with centrally located oval nuclei and scant amphophilic to eosinophilic cytoplasm. **B,** Striated ducts are larger than intercalated ducts and are lined by columnar cells with centrally located round nuclei displaying deep basal vertical striations. **C,** Transition from intercalated duct to striated duct. **D,** Small interlobular excretory duct lined by pseudostratified columnar cells and located within dense fibrous connective tissue.

Fig. 18-5. Immunohistochemical staining of salivary gland parenchyma.

Immunohistochemical reactivity in normal salivary gland structures include **(A)** high and low molecular weight cytokeratin (CAM 5.2) expression in acinar cells, intercalated cells and striated duct cells (*arrowheads*), and interlobular duct cells (*arrow*); myoepithelial and basal cells are also reactive; **(B)** high molecular weight cytokeratin (CK5/6) expression of myoepithelial cells of both acini and striated ducts (*arrowheads*) and basal cells of interlobular duct (*arrow*); **(C)** p63 expression seen in myoepithelial cells of acini (*left*) and basal cells of striated duct (*arrowhead*) and interlobular duct (*arrow*); **(D)** S100 protein expression in myoepithelial cells of acini and striated ducts (*arrowheads*) but negative in basal cells of interlobular duct (*arrow*); note adipocytes are also S100 protein positive; **(E)** calponin expression is similar to that of S100 protein, including expression in myoepithelial cells of acini and striated ducts (*arrows*) but negative in basal cells of interlobular duct (*arrowhead*); **(F)** discovered on GIST-1 (DOG1) expression is primarily restricted to acinar cells with moderate apical membranous staining.

- Immunohistochemical staining of acinar cells includes:
 - Pancytokeratins and low molecular weight cytokeratins (AE1/AE3, CAM5.2, CK7, CK8, CK19), EMA and CEA positive
 - Amylase positive
 - Discovered on GIST-1 (DOG-1) positive:
 - Diffuse moderate (2+) apical membranous staining pattern in normal serous acini, 1+ apical membranous pattern in mucous acini
 - Myoepithelial cells, striated and excretory ducts negative
 - p63, calponin, smooth muscle actin, S100 protein, and vimentin negative
 - High molecular weight keratins (e.g., CK5/6) typically negative
- Intercalated ducts
 - Lined by low cuboidal cells with centrally located oval nuclei and scant amphophilic to eosinophilic cytoplasm
 - More conspicuous in the parotid gland than in other salivary glands
 - Immunohistochemical staining of intercalated duct cells includes:
 - Pancytokeratins and low molecular weight cytokeratins (AE1/AE3, CAM5.2, CK7, CK8, CK19), EMA, CEA, and estrogen receptor positive
 - p63, calponin, smooth muscle actin, S100 protein, and vimentin negative
 - DOG-1 positive in distal intercalated cells:
 - Weak to moderate (1-2+) apical staining
 - Amylase negative
 - High molecular weight keratins (e.g., CK5/6) typically negative
- Myoepithelial cells:
 - Ectodermally derived, flat, elongated cells lying at the periphery of the acinar cells and the intercalated cells in the space between the basement membrane and the basal plasma membrane
 - Generally, myoepithelial cells are difficult to identify by light microscopy; appear as flattened, stellate, and spindle-shaped cells with cellular processes that extend around acini and intercalated ducts
 - Their contractile function is similar to smooth muscle, assisting in the movement of saliva through the duct system.
 - Immunohistochemical staining of myoepithelial cells includes:
 - Pancytokeratins, low and high molecular weight cytokeratins (AE1/AE3, CAM5.2, CK7, CK8, CK19) positive

TABLE 18-1 Salivary Gland Acinar Cell Types

Salivary Gland	Acinar Type*
Parotid	Serous (scattered mucous cells can be found)
Submandibular (submaxillary)	Serous and mucous
Sublingual	Mucous and serous
Palate	Mucous
Tongue	Mucous and serous
Buccal	Mucous and serous
Lip	Mucous and serous
All other upper aerodigestive tract sites	Mucous and serous

*Predominant type first.

Adapted from Ellis GL, Auclair PL: The normal salivary glands. In Silverberg SG, editor: Tumors of the salivary glands. AFIP Atlas of tumor pathology, series 4, fascicle 9, Washington, 2008, ARP Press.

TABLE 18-2 Immunohistochemistry: Normal Salivary Gland Structures

Cell	PanK	LMWK	HMWK	EMA	CEA	S100	p63	SMA	CAL	VIM	GFAP	DOG1
ED	+	+	–	+	+	–	–	–	–	–	–	–
SD	+	+	–	+	+	–	–	–	–	–	–	–
ID	+	+	–	+	+	–	–	–	–	–	–	+*
A	+	+	–	+	+	–	–	–	–	–	–	+ [†]
M	+	+	+	–	–	+	+	+	+	+	V+	–
B	+	+	+	–	–	–	+	–	–	+	–	–

A, Acinar cells; B, basal cells; CAL, calponin; CEA, carcinoembryonic antigen; DOG1, discovered on GIST 1; ED, excretory duct; EMA, epithelial membrane antigen; GFAP, glial fibrillary acidic protein; HMWK, high molecular weight cytokeratin (e.g., CK5/6); ID, intercalated duct; LMWK, low molecular weight cytokeratins (e.g., CK7, CK8, CK19); M, myoepithelial cells; PanK, pancytokeratin (AE1/AE3; CAM5.2); SD, striated duct; SMA, smooth muscle actin; V+, variably positive; VIM, vimentin.

*Weak to moderate apical staining.

[†]Moderate apical membranous staining.

- p63, calponin, smooth muscle actin, S100 protein, and vimentin positive
- Variable GFAP reactivity
- EMA and CEA negative
- DOG-1, amylase negative
- Striated ducts:
 - Larger than intercalated ducts
 - Lined by columnar cells with centrally located, round nuclei displaying deep basal vertical striations representing basal folds in plasma membranes for which these ducts are named
 - Due to large numbers of cytoplasmic mitochondria the cells of striated ducts:
 - Have prominent eosinophilic granular cytoplasm
 - Are intensely reactive with phosphotungstic acid-hematoxylin
 - Immunohistochemical staining of striated duct cells includes:
 - Pancytokeratins and low molecular weight cytokeratins (AE1/AE3, CAM5.2, CK7, CK8, CK19), EMA and CEA positive
 - p63, calponin, smooth muscle actin, S100 protein, and vimentin negative
 - DOG-1, amylase negative
 - High molecular weight keratins (e.g., CK5/6) typically negative
- Excretory (interlobular) ducts:
 - Lined by pseudostratified columnar cells adjacent to the striated duct cells
 - Goblet cells may be present intermixed among the pseudostratified columnar cells.
 - Lined by stratified squamous cells as these ducts merge with the oral mucosal epithelium
 - Immunohistochemical staining of excretory (interlobular) duct cells includes:
 - Pancytokeratins and low molecular weight cytokeratins (AE1/AE3, CAM5.2, CK7, CK8, CK19), EMA and CEA positive
 - p63, calponin, smooth muscle actin, S100 protein, and vimentin negative
 - DOG-1, amylase negative
 - High molecular weight keratins (e.g., CK5/6) typically negative
- Basal cells:
 - Located around striated and excretory (interlobular) ducts
 - Differ from myoepithelial cells by absence of myoid markers by immunohistochemistry and myofilaments on ultrastructural evaluation
 - Play role in regeneration and metaplastic changes
 - Immunohistochemical staining of basal cells includes:
 - Pancytokeratins, low and high molecular weight cytokeratins (AE1/AE3, CAM5.2, CK7, CK8, CK19) positive
 - p63 positive
 - Calponin, smooth muscle actin, S100 protein, and GFAP negative
 - EMA and CEA negative
 - DOG-1, amylase negative
- Salivary glandular component separated into lobules by fibrous tissue septa.
- Histologic differences between the salivary glands rests with the composition of their respective acinar cells:
 - Parotid gland:
 - Entirely serous although mucinous acini may be identified
 - Sebaceous glands and/or scattered sebaceous cells may be identified:
 - Stains for mucin are negative.
 - Mature adipose tissue is a normal finding in parotid gland parenchyma, and it proportionally increases with age.
 - Submandibular (submaxillary) gland:
 - Mixed serous and mucous with the majority of acinar cells being serous
 - Serous cells typically arranged as crescent-shaped caps (referred to as demilunes) along the periphery of the mucous acinar cells
 - Sublingual gland:
 - Mixed mucous and serous (demilunes) with the majority of acinar cells being mucous
 - Minor salivary glands vary depending on site:
 - Most of upper aerodigestive tract including oral cavity, sinonasal tract, pharynx, and larynx is seromucous, with the majority of acinar cells being mucous.
 - In anterior ventral portion of tongue (referred to as Blandin or Nunn glands) composed of pure mucous type
 - In the region of the circumvallate papillae on the posterior and lateral portions of the tongue (referred to as von Ebner glands) composed of pure serous type
 - Palate is purely mucous.
- Age-related and/or reactive cellular changes may include:
 - Oncocytes:
 - Characterized by cells with abundant eosinophilic granular cytoplasm owing to presence of abundant mitochondria
 - Uncommon cell type in salivary gland in patients under 50 years of age but presence increases with age
 - See Chapters 19 and 20 for more detailed discussion and illustrations.

- Sebaceous cells:
 - Present in most parotid glands but generally are few in number
 - Appear as small collections of sebaceous cells
 - Do not stain with mucicarmine.
 - Immunoreactive for EMA
- Fatty infiltration:
 - In particular relative to parotid gland represents a normal finding and proportionally increases with age
 - Presence increased under other conditions including but not limited to malnutrition (see next chapter)
- Metaplasia may include presence of:
 - Squamous cells with keratinization and intercellular bridges
 - Mucous cells
 - Metaplastic changes not infrequently seen after a traumatic event such as prior fine-needle aspiration or biopsy but may occur spontaneously unrelated to a traumatic event
- Hyperplasia
- Atrophy
- Age-related and metaplastic changes of salivary gland discussed in Chapter 19

Non-Neoplastic Diseases of Salivary Glands

CLASSIFICATION OF NON-NEOPLASTIC SALIVARY GLAND LESIONS

BOX 19-1 Classification of Non-Neoplastic Salivary Gland Lesions

Developmental Lesions

- Heterotopias

Hyperplasia and Metaplasia

- Adenomatoid hyperplasia
- Squamous metaplasia
- Necrotizing sialometaplasia
- Oncocytic changes (oncocytic metaplasia, oncocytosis)
- Intercalated duct lesions (intercalated duct hyperplasia; [intercalated duct adenoma])

True Cysts

- Lymphoepithelial cyst
- Salivary duct cyst
- Polycystic (dysgenetic) disease

Nondevelopmental Cysts

- Mucus extravasation phenomenon
- Mucus retention cyst
- Ranulas

Infectious, Inflammatory, and Autoimmune Disease

- Bacterial sialadenitis
- Mumps
- HIV salivary gland disease
- Chronic sialadenitis
 - Nonobstructive
 - Infectious
 - Noninfectious
 - Obstructive
 - Sialolithiasis
 - Sialadenosis
- IgG4-related sialadenitis
- Lymphoepithelial sialadenitis
 - Sjögren syndrome

DEVELOPMENTAL LESIONS

Heterotopic Salivary Glands

See Section 7, The Ear and Temporal Bone.

Definition: Salivary gland tissue located in sites other than those appropriate for the normal anatomic distribution of salivary glands.

Synonyms: Ectopic salivary glands; salivary gland choristoma

Clinical

- Majority of heterotopic salivary gland tissue occurs in head and neck sites.
- Most common locations include the periparotid lymph nodes, the middle ear, and the lower neck; less frequent sites of occurrence include:
 - Upper neck
 - External ear (auditory canal), middle ear
 - Intraosseous sites (e.g., mandible)
 - Cerebellopontine angle
 - Pituitary gland

- Salivary gland tissue has been reported in thyroglossal duct, capsules of the thyroid gland and parathyroid glands, mediastinum, tonsils, and gingiva, as well as more distant sites, including the prostate gland, vulva, and rectum.

Heterotopic Salivary Gland Tissue in the Lower Neck

- Most of these examples occur in the lower anterolateral neck along the medial border of the sternocleidomastoid muscle.
- Most common presenting symptom is a draining sinus on the anterior aspect of the neck along the medial border of the sternocleidomastoid muscle near the sternoclavicular joint.
- Sinuses drain saliva-like material, usually a very limited quantity but the amount may increase during meals.
- Localized nontender swelling associated with the sinus may be the only complaint.

- Histologically, the tissue includes normal salivary gland tissue either purely serous or mixed serous and mucinous glands.

Intranodal Periparotid Salivary Gland Tissue (Fig. 19-1)

- Not technically heterotopic but represents normal development
- Generally accepted explanation for the occurrence of salivary gland tissue in periparotid lymph nodes is entrapment during embryonic development rather than true ectopia, although this issue is still the subject of debate.

Fig. 19-1. Intranodal parotid parenchyma.

A, B, Periparotid lymph node with intranodal salivary gland parenchyma composed of all components of salivary gland parenchyma including serous acini and ducts. This is a normal and fairly frequent finding in periparotid lymph nodes believed to represent entrapment of salivary gland parenchyma during embryonic development rather than true ectopia.

- Ontogenically, the parotid gland is the last of the salivary glands to be encapsulated, resulting in either incorporation/entrapment of lymphoid tissue within the parotid or incorporation/entrapment of parotid ducts and acini within the periparotid lymph nodes epithelium.
- Histologically, the salivary gland tissue includes all components of the salivary gland unit including ducts and acini but more often consists of serous glands with scattered, well-formed ducts.
- All pathologic lesions (non-neoplastic and neoplastic) may originate from the intranodal salivary gland tissues, including:
 - Cysts, metaplasia, hyperplasia, and benign epithelial ductal proliferations
 - Benign and malignant salivary gland neoplasms:
 - Represent primary intranodal neoplasms with the gland proper being devoid of tumor
 - A malignancy arising from intranodal salivary gland tissue:
 - May present as mass lesion within the node separate from adjacent major salivary glands
 - In the absence of an identifiable primary neoplasm from an adjacent salivary gland, these intranodal foci can be considered as the primary site for the development of the malignancy.

Heterotopic Salivary Gland Tissue in the Middle Ear

See Section 7, The Ear and Temporal Bone.

- Heterotopic salivary gland tissue in the middle ear is discovered in the evaluation of patients for conductive hearing loss.
- Most cases are associated with ossicular abnormalities of the incus and stapes.
- Patients range in age from the first to sixth decades but most are under 21 years of age.
- Because the ossicles originate from the first (malleus and incus) and second (stapes) branchial arch, the presence of salivary gland tissue is considered a developmental abnormality involving the branchial arches.
- Heterotopic salivary gland tissue has been seen in association with anomalies that suggest the branchio-otorenal (BOR) syndrome; in addition, a syndrome including salivary gland choristoma in association with branchial arch abnormalities, most commonly the second, as well as abnormalities of the facial nerve, has been identified.
- Salivary gland tissue in the middle ear:
 - May extend into the eustachian tube, involve the mastoid bone, and may be intimately associated with the facial nerve

- Represents an admixture of seromucinous glands and adipose tissue; the latter contributes to the yellow appearance of the tissue
- Recapitulates the acinar arrangement of normal salivary glands; ducts may be identified
- Is situated within the submucosa
- In general conservative surgical resection is curative; however, this tissue is slow growing and in conjunction with potential complications from surgery, particular to the facial nerve surgical intervention may not be advised.
- A biopsy may be required to establish a diagnosis.

Intraosseous Heterotopic Salivary Gland Tissue

- Intraosseous salivary gland tissue is uncommon and tends to occur in the posterior mandible near the angle beneath the mandibular canal and less frequently in the anterior mandible.
- Intraosseous salivary gland tissue is asymptomatic and is an incidental radiographic finding.
- No treatment is required.

Salivary Gland Heterotopia and Salivary Gland Tumors

- Salivary gland neoplasms occurring in sites that normally do not contain salivary gland tissue are usually considered to originate from heterotopic salivary gland tissue.
- An exception to the above statement includes those salivary gland tumors arising in periparotid lymph nodes without an identifiable parotid gland mass:
 - Clinical setting is one in which the intranodal salivary gland tumor, specifically a malignant tumor, is considered as being of “unknown primary origin.”
 - Clinical and radiologic search for the primary salivary gland tumor proves negative.
 - Entrapment of salivary gland parenchyma within lymph nodes during embryonic development accounts for the intranodal salivary gland tissue.
 - Salivary gland neoplasms, benign and malignant, may originate within periparotid nodal salivary gland parenchyma presenting as a mass separate from adjacent major salivary glands (i.e., parotid gland).
 - In the absence of an identifiable primary neoplasm from an adjacent salivary gland, these intranodal foci can be considered as the primary site.
- A wide variety of tumor types occur in salivary gland heterotopia, including (but not limited to):

- Pleomorphic adenoma, monomorphic adenomas (e.g., Warthin tumor), acinic cell adenocarcinoma, mucoepidermoid carcinoma, adenoid cystic carcinoma, adenocarcinoma not otherwise specified, carcinoma ex pleomorphic adenoma, sialoblastoma, others

Accessory Parotid Gland

- Represent isolated lobules of parotid gland parenchyma separated from the main body of the gland situated along a major salivary duct
- Incidence reported up to 56% in an autopsy series
- Accessory parotid tissue is spheric or oblong, measuring from 0.5 to 3 cm in greatest dimension.
 - Accessory tissue can be seen anterior to the border of the masseter situated on the buccal fat pad.
 - Accessory tissue is normally connected to Stensen duct by a single accessory duct, although more than a single duct may be found.
- Clinically, lesions of accessory parotid tissue present with mass in the cheek.
- Histologically, accessory tissue is identical to the normally situated parotid tissue and reflects similar pathologic processes that the main gland may exhibit (e.g., inflammation, fatty infiltrate, other).
- Benign and malignant salivary gland tumors may arise in accessory parotid glands:
 - Benign tumors may include pleomorphic and monomorphic adenomas, Warthin tumor, others.
 - Malignant tumors reported include a wide variety of types, including (but not limited to) mucoepidermoid carcinoma, acinic cell adenocarcinoma, adenoid cystic carcinoma, carcinoma ex pleomorphic adenoma, others.
- Magnetic resonance imaging is helpful in the diagnosis and treatment of accessory parotid gland tumors.
- Best surgical approach to tumors in the accessory parotid region is via a standard parotid incision and concomitant superficial parotidectomy; this approach to accessory parotid gland tumors is superior in that it provides a better margin of resection and minimizes functional and cosmetic deformities.

HYPERPLASIA AND METAPLASIA IN THE SALIVARY GLANDS

Adenomatoid Hyperplasia of Mucous Salivary Glands (Fig. 19-2)

Definition: Hyperplastic or hamartomatous proliferation of the mucous acini of salivary gland tissue.

Fig. 19-2. Adenomatoid hyperplasia.

A, B, Adenomatoid hyperplasia showing submucosal proliferation of hyperplastic lobules of normal-appearing mucinous acini without significant inflammation or fibrosis; the overlying squamous epithelium (**A**) is unremarkable.

Clinical

- Relatively uncommon lesion that tends to occur slightly more often in men than in women
- Occurs in all age groups, although it is more common in adults than in children
- Majority of cases involve the hard or soft palates; less common sites of occurrence include the retromolar mucosa; involvement of major salivary glands has not been reported.
- Clinical presentation includes a localized painless mass often discovered during routine dental examination; ulceration of the overlying mucosa is not present:
 - Often mistaken for a salivary gland neoplasm
- Cause is unknown and there is no association with sialadenitis or trauma.

Pathology

Gross

- Lesions are firm and sessile, varying in size from 0.5 to 3 cm.

Histology

- Submucosal proliferations of hypertrophied and/or hyperplastic lobules of otherwise normal-appearing mucinous acini
- No significant inflammation or fibrosis are seen.
- Overlying epithelium is unremarkable, although pseudoepitheliomatous hyperplasia may be present.

Differential Diagnosis

- Salivary gland neoplasms:
 - Submucosal lobular configuration composed of a single cell type (i.e., mucinous acini) should allow for differentiation from benign and malignant salivary gland neoplasms.

Treatment and Prognosis

- Surgical excision is curative.

Squamous Metaplasia and Mucous Cell Metaplasia

- Relatively common metaplastic changes that can be seen in a wide variety of lesions, including non-neoplastic lesions and neoplasms (benign and malignant)
- May occur spontaneously or occur as secondary to a traumatic event such as fine-needle aspiration biopsy or biopsy
- For illustrations see Chapter 20 under Pleomorphic Adenoma and Warthin Tumor.

Necrotizing Sialometaplasia (NS)

(Figs. 19-3 through 19-6)

Definition: Benign, self-healing (reactive) inflammatory process of salivary gland tissue, which clinically and histologically may be mistaken for a malignant neoplasm.

Synonym: Adenometaplasia

Clinical

- Tends to affect men more than women; occurs over a wide age range with the average age of occurrence in the fifth and sixth decades of life
- Most commonly involves the intraoral minor salivary glands, particularly involving the palate:
 - Major salivary glands, as well as minor salivary glands of virtually every site in the upper aerodigestive tract, can be affected.

Fig. 19-3. Necrotizing sialometaplasia.

A, Necrotizing sialometaplasia (NS) of the palate appearing as a deep, crater-like ulcerative lesion. **B**, Less commonly NS may appear as a submucosal nodular swelling.

- Larynx may be affected but is a rare site of occurrence.
- Most common presenting problem is that of a painless ulcerated lesion or a nodular swelling, which is usually unilateral but may be bilateral:
 - May be associated with pain, numbness, or a burning sensation and dysphagia
 - Uncommonly, may present with anesthesia of the greater palatine nerves
- Pathogenesis:
 - Believed to be secondary to trauma and/or an ischemic event with compromise of the vascular supply to salivary glands leading to ischemic necrosis:
 - Ischemia may be iatrogenically induced after an operative procedures (surgery, postintubation, postbronchoscopy), anesthesia, or radiotherapy.
 - Mean duration of 18 days from the time of the insult to the development of the lesion
 - In experimental studies on rat submandibular and sublingual glands, the induction of

Fig. 19-4. Necrotizing sialometaplasia.

A, Low magnification shows submucosal lobular necrosis of the salivary glands consisting of acinus-sized pools of mucin with preservation of the lobular architecture; the surface squamous epithelium is intact. **B**, At higher magnification, the metaplastic minor salivary glands show rounded, smooth borders with bland squamous epithelial cells, uniform nuclei, and abundant eosinophilic cytoplasm with occasional preservation of ductal lumina; mucous cells are not seen.

sialometaplasia occurred 6 to 8 days after arterial ligation.

- Inciting event is primarily but not exclusively thought to be due to ischemia.
- May occur de novo unassociated with a traumatic event or it may occur in association with other non-neoplastic lesions or in association with a neoplasm (benign or malignant)

Pathology

Gross

- Typically appears as a deep, crater-like ulcerative lesion, measuring from 1 to 3 cm:
 - May appear as a submucosal nodular swelling that may slough, leaving a crater-like ulcer

Fig. 19-5. Necrotizing sialometaplasia.

Left, The features on routine sections are usually diagnostic but *(right)* mucin stains may be helpful in delineating the presence of residual mucous cells.

Histology

- At low magnification there is preservation of the lobular architecture of the minor salivary glands.
- Histologic hallmark is squamous metaplasia of residual acinar and ductal elements:
 - Squamous cells are typically bland in appearance with uniform nuclei and abundant eosinophilic cytoplasm.
 - Preservation of ductal lumina and/or scattered mucocytes may or may not be identified.
 - Lobular architecture is maintained and metaplastic lobules vary slightly to moderately in size and shape, have smooth edges.
 - Metaplastic foci may be surrounded by granulation tissue and mixed acute and chronic inflammatory reaction.
 - In some examples, the squamous metaplastic foci may be atypical, including irregular contours of metaplastic lobules with nuclear hyperchromasia, increased nuclear-to-cytoplasmic ratio, dyskeratosis, and mitoses, suggesting a possible diagnosis of squamous cell carcinoma:
 - Preservation of lobular architecture of the involved minor salivary glands should allow for differentiation from carcinoma but in any given example it may be challenging differentiating NS from squamous cell carcinoma.
 - Low proliferation rate (<10%) by Ki67 staining and absence of p53 reactivity may support a diagnosis of NS but do not unequivocally differentiate NS from squamous cell carcinoma.
 - Presence of myoepithelial cells along the periphery of the metaplastic lobules as determined by reactivity for myoepithelial

Fig. 19-6. Necrotizing sialometaplasia of the sinonasal tract.

A, Presence of lobular necrosis (*bottom left and center*) with adjacent metaplastic seromucous glands. **B**, At higher magnification the metaplastic epithelial cells are atypical characterized by the presence of nuclear pleomorphism, hyperchromasia, increased nuclear-to-cytoplasmic ratio and individual cell necrosis raising the concern for a possible diagnosis of squamous cell carcinoma. However, based on the overall architectural findings including preservation of lobular architecture of the minor salivary glands and absence of definitive evidence of invasive growth, the findings support a diagnosis of necrotizing sialometaplasia. Long-term follow-up of the patient proved the lesion to be benign with no recurrence or progression of disease.

cell-related markers (e.g., p63, calponin, smooth muscle actin) and keratin subtypes in NS suggested as possible differentiating findings from squamous cell carcinoma but do not unequivocally differentiate NS from squamous cell carcinoma

- Necrotic lobules consist of acinus-sized pools of mucin, which may extend into adjacent tissue, eliciting a granulation tissue reaction with associated acute and chronic inflammation:
 - Necrotic lobules may not be present in all cases so that the designation of sialometaplasia without

“necrotizing” would be more appropriate in such a situation.

- With regeneration, mitoses, individual cell necrosis, enlarged nuclei, and prominent nucleoli can be seen.
- Associated findings include ulcerated mucosa and pseudoepitheliomatous hyperplasia (PEH):
 - PEH results when the metaplastic lobules present in excretory ducts and merge with surface epithelium.
 - This reaction may be so striking, presenting a diagnostic nightmare in separation from an infiltrating squamous cell carcinoma.
- Histochemistry:
 - Intraluminal and/or intracytoplasmic mucicarmine and diastase-resistant, PAS-positive material may be identified.

Differential Diagnosis (Table 19-1)

- Mucoepidermoid carcinoma
- Adenosquamous carcinoma
- Squamous cell carcinoma

NOTE: The retention of the overall lobular architecture, bland appearance of the squamous nests with rounded or smooth edges, and retention of residual ductal lumina and mucocytes help in differentiating NS from the malignant neoplasms listed above.

Treatment and Prognosis

- NS are self-limiting lesions that heal by secondary intention:
 - Depending on the size of the lesion, the healing process in most cases occurs from 3 to 12 weeks.
 - Debridement and saline rinses may aid in the healing process.
- Recurrences do not usually occur.

Subacute Necrotizing Sialadenitis (SANS)

- Nonspecific inflammatory condition of unknown cause affecting oral minor salivary glands:
 - Some authorities believe that SANS should not be included within the spectrum of necrotizing sialometaplasia and most likely represents an infectious process or perhaps an immune response to an unknown allergen.
 - Other authorities believe SANS may represent the early or minimal form of NS.
- In either case, SANS most often is characterized by a localized palatal swelling, accompanied by an abrupt onset of pain.
- Patients range in age from 15 to 45 years, with a mean age of 21.9 years.

TABLE 19-1 Necrotizing Sialometaplasia: Differential Diagnosis

	NS	MEC, Low-Grade	SCC
Architecture/growth	Retention of lobular architecture	Cystic and solid; may be circumscribed to encapsulated without invasion or show infiltrative growth	Haphazard, infiltrative growth
Cellular components	Smooth round to oval nests of metaplastic squamous epithelium with bland cytology; may show residual ductal lumina with mucous cells	Admixture of mucous, intermediate (“basaloid”) and epidermoid (squamous) cells; bland cytology; irregular cell nests	Nests and cords of squamous cells with irregular outlines and variable amount of cytologic atypia; may entrap residual glands but the tumor itself contains no mucin
Cyst formation	Absent	Present (prominent component)	Absent
Surface epithelium	May show PEH; usually not connected with NS	Uninvolved; not connected with tumor	Often dysplastic and/or in direct continuity with the carcinoma; may be ulcerated
Extravasated mucin	May be present	May be present	Absent
Necrosis of salivary gland lobules	May or may not be present	Absent	Absent
Inflammation	May be prominent	May be prominent with mucin extravasation	May be present; associated desmoplasia
Cytogenetics	None known	<i>CRTC1-MAML2</i> translocation	None known

MEC, Mucoepidermoid carcinoma; NS, necrotizing sialometaplasia; PEH, pseudoepitheliomatous hyperplasia; SCC, squamous cell carcinoma.

- SANS most often affects intraoral sites, including the hard palate, soft palate, buccal mucosa, and tonsils.
- Lesions typically are nonulcerated swellings, develop over a short period of time (7 to 10 days), and range in size from 0.3 to 2.5 cm in diameter.
- Histopathologic features include:
 - Diffuse involvement of minor salivary glands by lymphocytes, histiocytes, neutrophils, and variably by eosinophils
 - Loss of acinar cells, early acinar cell necrosis surrounded by a dense polymorphous inflammatory infiltrate, and atrophy of ductal cells
 - Squamous metaplasia is not usually seen.
- Appears to be a self-limiting process with most cases resolving 2 to 3 weeks after biopsy without recurrences
- Main differences between SANS and NS include:
 - SANS is usually a smaller-sized lesion than lesions of NS.
 - Scarcity of ulceration in SANS but typically present in NS
 - Absence of squamous metaplasia in SANS but present in NS

Oncocytic Alterations

- Oncocytic cells in the salivary glands occur in the following settings:
 - Oncocytic metaplasia
 - Oncocytosis (nodular or diffuse)
 - Oncocytoma; oncocytic carcinoma
 - Warthin tumor
 - Variety of other lesions/tumors that may have oncocytic cells including but not limited to:
 - Pleomorphic adenoma
 - Basal cell adenoma
 - Myoepithelioma
 - Canalicular adenoma
 - Mucoepidermoid carcinoma
 - Acinic cell carcinoma
 - Others

Oncocytic Metaplasia (Fig. 19-7)

- Non-neoplastic transformation of ductal and acinar epithelium to oncocytes:
 - Oncocytes are histologically characterized by cytoplasmic alteration (metaplasia) of epithelial and/or myoepithelial cells with swelling of the cytoplasm by mitochondrial hyperplasia giving the cell a characteristic granular eosinophilic appearance by light microscopy.
- Represents an aging phenomenon:
 - Oncocytic metaplasia is generally not seen in patients less than 50 years of age from which time

Fig. 19-7. Oncocytic metaplasia.

A, Incidentally identified focus of oncocytic metaplasia (arrows) in a parotid gland from an older aged individual.
B, Oncocytic cells are characterized by the presence of granular eosinophilic cytoplasm.

the percentage of the population with oncocytic metaplasia increases.

- In contrast to oncocytoma (and oncocytosis), oncocytic metaplasia is non-mass-forming focal or limited changes in one or more areas within the salivary gland.
- Appear as isolated clusters of oncocytic cells within otherwise normal-appearing parenchyma
- Clear cell changes may be present.
- Usually represents incidental histologic findings in salivary glands excised for other reasons
- Oncocytic cells may be seen in other non-neoplastic processes (see oncocytosis immediately following), as well as in numerous salivary gland tumors, including pleomorphic adenomas, Warthin tumor, oncocytoma, mucoepidermoid carcinoma, acinic cell carcinoma, oncocytic carcinoma, others.

Oncocytosis (Fig. 19-8)

- Oncocytosis (also referred to as oncocytic [adenomatous] hyperplasia) represents a non-neoplastic mass-forming proliferation of oncocytic cells within the salivary gland.
- Typically appear as nodular foci, referred to as nodular oncocytic hyperplasia or nodular oncocytosis
- Less commonly, may represent a diffuse alteration in the affected salivary gland referred to as diffuse oncocytosis
- In either nodular or diffuse form may present as a clinically detectable mass lesion presenting difficulties in differentiation from oncocytoma
- Histologically, oncocytotic foci:
 - Include multiple (often two or more) separate nodules
 - Unencapsulated
 - Gradual merge with and/or contain residual (nononcocytic) salivary gland parenchyma, including ductular epithelium and serous acinar cells
 - Such histologic findings assist in differentiating oncocytosis from oncocytoma, the latter entirely composed of oncocytes without identifiable residual normal parenchyma.
 - May show clear cell change
- Differentiation of oncocytosis from oncocytoma may not be possible due to overlapping histologic features, and this differentiation may be more of an academic than practical issue because treatment and prognosis are essentially similar (i.e., cured by excision).

Intercalated Duct Lesions (IDL)

(Fig. 19-9)

Definition: Rare lesions that include hyperplasia, adenoma, or both (hybrid) that may be a precursor lesion of salivary gland neoplasms:

- Proposal that IDL may represent precursor lesion to salivary gland neoplasms based on presence of small foci of IDL in cases of basal cell adenoma, epithelial-myoepithelial carcinoma, pleomorphic adenoma, mucoepidermoid carcinoma, basal cell adenocarcinoma, Warthin tumor, acinic cell carcinoma, others
- Role as a precursor lesion not definitively proven

Clinical

- Rare lesion
- More common in females than in males; occur over a wide age range from second to ninth decades with a mean in the sixth decade
- Majority occur in the parotid gland > oral cavity > submandibular gland.

Fig. 19-8. Oncocytosis.

A, Mass-forming oncocytic nodule that is circumscribed but not encapsulated gradually merging with (*arrowheads*) and incorporating (*arrows*) residual salivary gland parenchyma. Higher magnification shows the (**B**) absence of a capsule and (**C**) presence of acini within oncocytic cells characterized by the presence of cells with granular eosinophilic cytoplasm.

Fig. 19-9. Intercalated duct hyperplasia.

A and **B**, Intraparotid relatively circumscribed but unencapsulated cellular proliferation composed of closely packed ducts that includes acinar cells along the periphery as well as within the lesion; stromal hyalinization focally around ducts is present. **C**, Closely packed ducts and incorporation of acinar cells within and along the periphery of the proliferation. **D**, Ducts are lined by cuboidal cells with small round nuclei and eosinophilic cytoplasm. There is an absence of nuclear pleomorphism or increased mitotic activity; acinar cells characterized by intracytoplasm basophilic (zymogen) granules are seen.

- Typically represent incidental finding found in association with another lesion
- Usually a small lesion measuring less than 5 mm in greatest dimension

Pathology

Intercalated Duct Hyperplasia

- Most common type of IDL
- Characterized by unifocal or multifocal (and diffuse) unencapsulated proliferation of small ducts with minimal intervening stroma merging/blending imperceptively with acinar and mucous cells of surrounding salivary gland parenchyma
- At low magnification appear as irregular pale foci contrasted with the surrounding darker-appearing salivary gland parenchyma:
 - In multifocal lesions, foci vary in size and shape.
- Intercalated ducts are lined by single layer of cuboidal to columnar cells with small round nuclei and eosinophilic to amphophilic cytoplasm:
 - There is an absence of nuclear pleomorphism or increased mitotic activity.
- Acinar cells may be incorporated within the proliferation and/or also identified at the periphery of most lesions.
- Myoepithelial cells are consistently present around the ducts but are not discernible by light microscopy requiring immunohistochemical staining with p63 or other markers (e.g., calponin, CK14, others) for identification.
- Stromal hyalinization that may be periductal can be identified.

- Other uncommon features may include:
 - Perilesional follicular lymphoid hyperplasia
 - Clear myoepithelial cells
 - Entrapment of nerve within the lesion
 - Presence of focal luminal eosinophilic secretions
 - Cystic change
 - Basal lamina-like material with a cribriform pattern
 - Absence of fat cells or intralesional inflammatory infiltrates

Intercalated Duct Adenoma

- Presence of discrete, rounded, partially to completely encapsulated nodules with well-defined contours
 - Fibrous capsule may vary in thickness and may contain entrapped, irregular-appearing ducts.
- Composed of intercalated ducts lined by a single layer of cuboidal to columnar cells with small round nuclei and eosinophilic to amphophilic cytoplasm:
 - There is an absence of nuclear pleomorphism or increased mitotic activity.
 - Minimal intervening stroma present
- Occasionally acinar cells may be interspersed among the ductular structures.

Hybrid Intercalated Duct Lesion

- Least common type of IDL
 - Partially round, encapsulated adenoma-like appearance admixed with irregular hyperplasia-like areas
 - Give the impression of a transition from hyperplastic intercalated ducts to adenomatous areas
- Alternatively may include a completely encapsulated adenoma with separate discrete, hyperplastic foci immediately adjacent to the capsule.
 - Entrapped irregular ductal structures can be identified within capsule of the adenoma.
- Clear intercalated duct cells may be present.
- Immunohistochemistry
 - CK7, S100 protein, estrogen receptor, lysozyme positive; progesterone receptor negative
 - Myoepithelial cells positive for calponin and CK14

Treatment and Prognosis

- No specific treatment required
- Given their usual small size typically cured in the excision without known untoward biology
- More critical issues relative to treatment and prognosis relate to associated neoplasms some of which include malignant salivary gland neoplasms (see under definition earlier).

TRUE CYSTS OF MAJOR SALIVARY GLANDS (SIALOCYSTS)

- Most cystic lesions of major salivary glands represent cystic neoplasms.
- True cysts differ from pseudocysts by the presence of an epithelial lining.
- Most true cysts of major salivary gland arise in the parotid gland and are divided into three general categories:
 - Lymphoepithelial cyst
 - Salivary duct cyst
 - Polycystic (dysgenetic) disease

Lymphoepithelial Cyst (LEC)

(Fig. 19-10)

Definition: Benign true cystic lesion of the parotid gland of uncertain origin with characteristic histology and unrelated to human immunodeficiency virus (HIV) infection.

Clinical

- Uncommon acquired parotid gland cyst
- Slightly more common in men than in women; occurs over a wide age range including at birth to the eighth decade of life; the average age is in the fifth decade of life
 - May be present at birth but the clinical manifestations may not become apparent until adult life
- Presents as painless swelling of the parotid gland
- Majority are unilateral although bilateral lesions may occur.
- May occasionally be tender or painful, which may be due to secondary infection
- Rarely, may be associated with facial paralysis
- Histogenesis remains controversial:
 - Suggested to originate from the branchial apparatus and/or develop from salivary gland inclusions in lymph nodes
 - Designation of lymphoepithelial cyst is histologically accurate and is more appropriate than branchial cleft cyst.
 - Some authors believe that LECs, as well as salivary duct cysts and dysgenetic or congenital cysts, arise from salivary ducts and have no relation with the branchial apparatus.

Pathology

Gross

- Cyst is usually sharply circumscribed, fluctuant and unilocular, rubbery to firm ranging in size from 0.5 to 6 cm in greatest dimension
- Multilocular cysts are uncommon.

Fig. 19-10. Parotid gland lymphoepithelial cyst.

A, The cystic proliferation is sharply delineated from the parotid parenchyma (*lower left*). **B** and **C**, Cyst is lined by benign squamous epithelium and the cyst wall includes a dense lymphoid cell proliferation including germinal centers. **D**, Intraepithelial mucous cells (*arrow*) can be found.

- On cut section, small intracystic protrusions may be present, imparting a granular appearance to the lesion; the latter correlate to the presence of the lymphoid component in the cyst wall (see later).
- Usually contain caseous material with a yellow-white appearance

Histology

- Sharply circumscribed from the surrounding parotid parenchyma and is separated from the parotid tissue by fibrous tissue
- Lined by a variety of epithelial cell types, including squamous, cuboidal, columnar, and pseudostratified types; mucous (goblet) cells, sebaceous cells, and oncocytic metaplasia may be present.
- Cyst wall composed of an abundant mature lymphoid cell proliferation with readily identifiable germinal centers

Immunohistochemistry:

- Lymphoid component shows expression for B-cell (CD20, others) and T-cell (CD3, others) markers.
- Absence of Epstein-Barr virus (e.g., in situ hybridization for Epstein-Barr encoded RNA)
- Absence of p24 staining (marker for HIV infection)

Differential Diagnosis

- Other salivary gland true cysts, as well as cystic neoplasms:
 - LECs may be mistaken for cystic lymphoepithelial sialadenitis (LESA):
 - In contrast to LECs, the cystic LESA has:
 - Characteristic lymphoepithelial cell lesions
 - Tendency of the lymphocytes to migrate through the epithelial component
 - Cystic LESA lack features that can be seen in LECs, including mucous (goblet) cells.

- HIV-salivary gland disease (see later in this chapter):
 - Histology of LECs is similar to cystic lymphoepithelial lesions in HIV-associated salivary gland disease.
 - Absence of features that might suggest associated with HIV infection including absence of:
 - Florid follicular hyperplasia
 - Multinucleated giant cells
 - Lymphoepithelial cell islands
 - Presence of p24 immunoreactivity in HIV-associated lesions
 - Marked decrease in interfollicular CD4:CD8 ratio observed in HIV+ compared with the HIV negative cases
- Among the cystic neoplasms of the parotid that LECs may be confused with is Warthin tumor and cystic mucoepidermoid carcinoma (cystic MEC):
 - In contrast to Warthin tumor, LECs are unilocular, lack papillary architecture, and lack an epithelial cell component with oncocytic cytoplasmic changes.
 - Cystic MECs are usually low-grade malignancies characterized by the presence of an admixture of mucous cells, epidermoid cells, and intermediate cells.
 - These three cell types are absent in LEC.
 - Further, MECs tend to be infiltrative neoplasms, a feature that is not present in LECs.
- Confusion with metastatic cystic squamous cell carcinoma may occur, but LECs lack the cytologic atypia and increased mitotic activity usually seen in metastatic cystic squamous cell carcinoma.

Treatment and Prognosis

- Surgical excision is curative.

Salivary Duct Cyst (Fig. 19-11)

Definition: Acquired cyst believed to develop due to ductal obstruction with marked cystic dilation of a salivary gland duct.

Synonyms: Acquired, simple, and retention cyst

Clinical

- Most common salivary gland cysts
 - Represent approximately 2% to 3% of all parotid gland lesions
- No gender predilection; occur over a wide age range from early childhood to older adults but most patients are over 30 years of age
- Clinical presentation includes unilateral painless swelling.

- Approximately 85% occur in the parotid gland with 10% in submandibular gland; remainder in various other salivary gland sites.
- Obstructive changes that may result in the development of the salivary duct cyst include neoplasms, postinflammatory strictures, calculi, and mucus plugs.

Pathology

Gross

- Well-circumscribed and are usually uniloculated containing thin, watery, to viscous brown fluid
- Majority are 1 to 3 cm, although may reach as large as 10 cm.

Histology

- Sharply demarcated from the adjacent salivary gland parenchyma
- Epithelium lining of the cysts may be single or multilayered cuboidal, columnar, or squamous epithelium; mucus-containing goblet cells and oncocytic metaplasia may be seen.
- Cyst wall is composed of collagenized connective tissue of varying thickness.
- Sparse to minimal chronic inflammatory cell infiltrate can be present.
- Granulomatous inflammation may be present in the cyst wall and in the adjacent gland.
- Adjacent salivary gland parenchyma may show duct ectasia with inspissated secretions and chronic inflammation.

Differential Diagnosis

- Lymphoepithelial cyst:
 - Marked inflammatory cell component typically seen in lymphoepithelial cysts is not seen in salivary duct cysts.
- Cystic neoplasms in particular mucoepidermoid carcinoma:
 - In contrast to cystic mucoepidermoid carcinoma (MEC), salivary duct cysts lack the proliferative (hyperplastic) cellular features as well as combination of cell types (i.e., epidermoid cells, mucocytes and intermediate cells) seen in MEC:
 - Infiltrative growth would further support a diagnosis of a malignant neoplasm but a number of malignant salivary gland neoplasms including MEC may not be infiltrative and still represent a carcinoma (see Chapter 20 for more complete discussion).

Treatment and Prognosis

- Surgical excision is curative.
- Rarely, salivary gland neoplasms have been associated with salivary duct cysts.

Fig. 19-11. Salivary duct cyst.

A, Unilocular cyst with fibrotic wall delineated from atrophic-appearing parotid parenchyma (*bottom*). The cyst is variably lined by **(B)** flattened (attenuated) epithelium, **(C)** cuboidal epithelium; **(D)** single to multilayered columnar epithelium; **(E)** mucous cells usually interspersed with nonmucous cells.

Polycystic (Dysgenetic) Disease (Fig. 19-12)

Definition: Rare developmental abnormality of the salivary gland duct system histologically similar to polycystic diseases of other organs (e.g., kidney, liver, pancreas, and lungs).

Clinical

- Polycystic disease represents approximately 0.2% of benign salivary gland cysts with less than 20 cases reported in the world literature.
- The overwhelming majority of the reported cases involve the parotid gland with rare involvement of the submandibular gland.

- Women are almost always affected and the majority of cases occur in childhood although patients range in age from the first to the seventh decade of life.
- Most patients have bilateral gland involvement, but occasionally only a single gland is involved.
- The clinical presentation includes recurrent, painless swelling with abnormalities in the flow of saliva.
- Based on a single case of familial occurrence, an autosomal dominant mode of transmission has been suggested.

Pathology

Cytology

- Aspirate smears characterized by relatively clean background, in which are distributed histiocytes, red

Fig. 19-12. Polycystic dysgenetic disease.

A and B, The involved gland is diffusely replaced by multiple varying-sized epithelial-lined cysts creating a honeycomb or lattice-like appearance. **C,** Cysts are lined by flattened to cuboidal to columnar-appearing epithelium; intraluminal proteinaceous and eosinophilic concretions with concentric laminations resembling microliths are present. **D,** Apocrine-like snouting may be present; entrapped salivary gland acini and ducts can be seen in between the cysts. Minimal inflammation is present.

blood cells, and small clusters of ductal epithelial cells

- Characteristic eosinophilic laminated spheroliths lie in many of the cystic spaces.

Gross

- On cut section the enlarged gland is spongy in consistency with apparent variable-sized cysts.

Histology

- Dominated by the presence of multiple varying-sized epithelial-lined cysts diffusely involving the affected gland(s):
 - Cysts have honeycomb, lattice-like appearances.
- Cysts are lined by flattened to cuboidal to columnar-appearing epithelium with apocrine-like snouting, and cytoplasmic eosinophilia.
- Some cells may contain lipid, creating a vacuolated or microvesicular appearance to the cytoplasm.
- Cysts vary in size and may be empty or contain inspissated proteinaceous material, as well as eosinophilic concretions that may demonstrate concentric laminations resembling microliths:
 - Eosinophilic concretions are diastase-resistant periodic acid Schiff positive.
 - Concretions may also stain for amyloid.
- Cysts replace the parenchyma, creating a honeycomb appearance.
- Despite parenchymal replacement, the overall lobular architecture of the gland is retained.
- Cysts often interconnect with incomplete fibrous septa.
- Parenchyma in between the cysts is fibrous but residual (entrapped) salivary gland acini and ducts can be seen.
- Inflammation is minimal to absent; no association with acute or chronic sialadenitis.

Differential Diagnosis

- Sclerosing polycystic adenosis (see Chapter 20):
 - Unilateral well-circumscribed and partially encapsulated lesion considered to be a neoplasm based on evidence of clonality and capability to harbor dysplasia and carcinoma in situ of ductal epithelium
- Cystic salivary gland neoplasms, including cystadenoma, cystadenocarcinoma, mucoepidermoid carcinoma:
 - In contrast to a neoplastic proliferation where the disease process is localized, the changes associated with polycystic disease diffusely involve the affected gland(s).
 - Absence of the constituent cells of mucoepidermoid carcinoma, including mucous cells, epidermoid cells, and intermediate assist in excluding a diagnosis of mucoepidermoid carcinoma.

Treatment and Prognosis

- Polycystic disease can be managed conservatively without surgical resection; however, surgical intervention may be required to establish a diagnosis or for cosmesis.
- This is a benign disorder with excellent long-term prognosis.
- To date, there is no evidence to suggest that polycystic salivary gland disease is associated with cystic lesions of other organs.

NONDEVELOPMENTAL CYSTS

- Salivary gland mucocele is a general term used to describe minor salivary gland lesions resulting from obstruction secondary to a mucous plug or intraluminal sialolith resulting in a mucus retention cyst, or due to trauma resulting in mucus extravasation phenomenon.

Mucus Extravasation Phenomenon

(Figs. 19-13 and 19-14)

Definition: Dilatation of minor salivary glands with accumulated mucus secretion often associated with mucus extravasation into the connective tissue without an associated epithelial lining.

Synonyms: Mucus escape phenomenon; extravasation mucocele

Clinical

- Relatively common lesion
- No gender predilection; occur in all age groups but are most common in the second to third decades of life
- Most common site of occurrence is lower lip, although other sites may be affected, including the buccal mucosa, floor of mouth, palate, tongue, retromolar fossa, tonsillar region, and upper lip.
- Clinical presentation varies but most common presentation is that of a painless swelling developing from days to week, then ruptures and disappears only to recur within several weeks.
- Superficial lesions present as raised swelling that is fluctuant on palpation.
- If the lesion is close to the surface, the overlying epithelium may be thin and the lesion has a translucent, bluish appearance; deeper-seated lesions located in soft tissues are more nodular and depending on the depth:
 - Superficial lesions are movable, smooth, soft to firm, raised vesicles with a blue or green appearance measuring in size from a few millimeters to several centimeters.

Fig. 19-13. Mucus extravasation phenomenon.

A, B, Mucus extravasation phenomenon of the lip appearing as superficial raised vesicles with a bluish appearance.

- Deeper-seated lesions are movable, firm, nodular, and covered by normal-appearing mucosa.

Pathology

Histology

- Characterized by extravasation of mucus into adjacent tissue intermixed with granulation tissue and inflammatory cells:
 - Lined by granulation tissue
 - Inflammatory cells may include numerous foamy histiocytes.
- Associated minor salivary glands show variable degree of atrophy, ductal dilatation, fibrosis, and a chronic inflammatory cell infiltrate.
- Overlying epithelium of the involved site is intact and often thinned.
- Histochemistry:
 - Intraluminal and intramural mucus material is mucicarmine and diastase-resistant, PAS positive.
 - These stains are useful for identifying residual mucus in the lesion.

Differential Diagnosis

- Diagnosis is usually straightforward and given the absence of epithelial lining essentially excludes all epithelial-lined cystic lesions (non-neoplastic and neoplastic).

Treatment and Prognosis

- Surgical excision is the preferred treatment to include excision of the associated salivary gland acini to prevent recurrence.
- Except in cases treated by inadequate surgery (incision), recurrences rarely occur.

Mucus Retention Cyst (Fig. 19-15)

Definition: Obstructive disorder of salivary glands resulting in ductal dilatation with increased intraluminal pressure; mucus retention cyst represents a true cyst in that an epithelial lining is present.

Synonyms: Retention mucocele; oral sialocyst

Clinical

- Relatively uncommon
- Tend to be slightly more common in men than in women; occur over a wide age range but most often occur in the sixth to eighth decades of life
- May occur in minor and major salivary glands but most common site of occurrence is the floor of mouth, buccal mucosa, and the lips
- Usually slow-growing and painless, appearing as a circumscribed and often fluctuant swelling; rarely, associated pain or a burning sensation may be present.
- Exact classification is subject of some debate:
 - Some classify this lesion with the more common mucus extravasation phenomenon.
 - Others consider it as a separate unique entity.
 - Given differences in clinical and histologic findings, there is justification for separating these entities.

Pathology

Gross

- Superficial lesions appear vesicular and bluish; deeper situated lesions are nodular and have the same color as the associated soft tissue.

Histology

- Cysts usually unilocular but may be convoluted simulating a multilocular or multicystic pattern
- True epithelial lined cysts:
 - Typically, epithelial lining consists of a uniform layer of cuboidal, columnar, or nonkeratinizing squamous epithelium; occasional mucus-secreting cells can be found.

Fig. 19-14. Mucus extravasation phenomenon.

A, Mucus extravasation phenomenon characterized by a well-circumscribed submucosal mucin-filled cystic lesion. Cyst lining includes **(B)** granulation tissue and/or **(C)** inflammatory cells; intraluminal and intramural mucinous material is positive for **(D)** mucicarmine (weakly) and **(E)** PAS with diastase.

Fig. 19-15. Mucus retention cyst.

A, Unilocular mucin-filled submucosal cyst. **B**, Cyst has an epithelial lining composed of a uniform layer of cuboidal nonkeratinizing squamous epithelium.

- Cyst filled with eosinophilic material that stains with mucicarmine and PAS with diastase
- Significant associated inflammatory cell infiltrate is not typically present.

Differential Diagnosis

- Diagnosis of mucus retention cyst is usually straightforward, although in any given case the differential diagnosis includes a salivary gland neoplasm such as a mucoepidermoid carcinoma.
 - Absence of identifying the cellular components of mucoepidermoid carcinoma (i.e., mucous cells, epidermoid cells and intermediate cells) plus the absence of invasive growth exclude this diagnostic consideration.

Treatment and Prognosis

- Surgical excision is curative.

Fig. 19-16. Simple ranula.

Simple ranula identified as a large, fluid-filled mass in the lateral aspect of the floor of the mouth.

Ranula (Fig. 19-16)

Definition: Form of mucus retention cyst or mucus extravasation phenomenon specifically occurring in the floor of the mouth in association with the ducts of the sublingual or submaxillary gland.

- In Latin, ranula means “frog-like” and is so named due to its bluish appearance, likened to a frog’s belly.

Clinical

- Rare as compared with the mucus escape phenomenon (extravasation mucocele)
- No gender predilection; may affect any age group
- Most commonly a unilateral lesion but may be bilateral
- Cause considered similar to usual mucocele.
- Ranulas are divided into two types:
 - Simple ranula:
 - Considered a true cyst based on the presence of an epithelial lining
 - Plunging ranula:
 - Considered a pseudocyst based on absence of an associated epithelial lining

Simple Ranula (Sublingual Ranula)

- Occurs in lateral aspect of the floor of the mouth
- Most frequently associated with sublingual gland:
 - Occasionally may be associated with submandibular gland
- Presenting symptoms include loud snoring and a painless mass; if large, deviation of the tongue may occur.

Pathology

Gross

- Fluctuant masses measuring up to several centimeters

- Superficial lesions may impart a bluish color; more commonly, the lesions are deep-seated with the color of the overlying intact mucosa.

Histology

- May be a unilocular or multilocular cystic lesion
- Often associated with an epithelial lining; the latter including squamous, cuboidal, or columnar cells
- Cysts contain amorphous eosinophilic material.

Differential Diagnosis

- Epidermoid cyst
- Pleomorphic adenoma
- Lipoma

NOTE: The histologic findings relative to all of the above-listed lesions readily differentiate these entities from a simple ranula.

Treatment and Prognosis

- Surgical excision, including removal of the entire associated salivary gland, is the treatment of choice; some authorities prefer to simply unroof the lesion (marsupialization of the cyst wall) rather than performing total excision.
- Inadequate excision occasionally results in recurrence.

Plunging Ranula (Deep Ranula)

(Figs. 19-17 and 19-18)

- Extends beyond mucous membranes with herniation through the mylohyoid muscle into the neck resulting from mucus extravasation
- Clinical presentation is that of a painless neck mass in the submental or submandibular triangle with or without an associated lesion in the floor of the mouth.

Pathology

Histology

- Appear as pools of mucus surrounded by fibrous tissue, chronic inflammatory cells, including histiocytes
- Associated epithelial lining is not seen.
- Mucicarmine and PAS with diastase staining helpful in identifying extravasated material as mucus

Differential Diagnosis

- Epidermoid cyst
- Thyroglossal duct cyst
- Cystic hygroma
- Branchial cleft cysts

NOTE: The histologic findings and anatomic localization relative to all of the above-listed lesions readily differentiates these entities from a plunging ranula.

Fig. 19-17. Plunging ranula.

Plunging ranula in which there is herniation from the floor of the mouth through the mylohyoid muscle with a painless mass in (A) the submandibular area and (B) in the submental area.

Fig. 19-18. Plunging ranula.

Left, Histologically, plunging ranulas appear as mucinous material surrounded by fibrous tissue, chronic inflammatory cells including histiocytes without an associated epithelial lining. *Right*, Mucicarmine staining shows the presence of weakly positive mucin material within the fibroinflammatory tissue.

Treatment and Prognosis

- Meticulous excision of the lesion including excision of the associated salivary gland of origin is the preferred treatment.
- Failure to include resection of the salivary gland results in recurrence.

INFECTIOUS, INFLAMMATORY, AUTOIMMUNE LESIONS OF SALIVARY GLANDS

Sialadenitis

Definition: Acute, subacute, or chronic inflammation of salivary glands due to a variety of causes including infectious disease, inflammatory condition, part of a systemic or localized autoimmune disease, secondary to trauma or secondary to stone formation.

- Sialadenitis may be acute or chronic and result from obstructive or nonobstructive causes.
- Nonobstructive sialadenitides are generally caused by an infectious agent and are divided into acute and chronic forms.

Acute Nonobstructive (Infectious) Sialadenitis

Clinical

- Infections of salivary glands may occur in a previously healthy gland or may result from a decrease in

the function of the gland secondary to physiologic dysfunction or to an anatomic barrier.

- Microorganisms may gain access to the gland via retrograde extension through the ductal system, lymphatic spread to intraglandular lymph nodes, or by hematogenous routes.
- Acute sialadenitis most commonly affects the parotid and submandibular glands.
- Acute sialadenitis may be bacterial or viral in origin:
 - *Staphylococcus aureus* and *Streptococcus viridans* are the most commonly cultured bacteria, but anaerobic bacteria have also been implicated in a significant number of cases.
 - Most common viral illness infecting the salivary glands is epidemic parotitis, also referred to as mumps, the causative organism being an RNA virus in the Paramyxovirus group:
 - Patients who are serologically negative for mumps may have infection caused by other viruses including Cocksackie A, ECHO, Epstein-Barr virus, cytomegalovirus, parainfluenza virus type C, and lymphocytic choriomeningitis virus.
 - In addition, the salivary glands represent a site of involvement for human immune virus (HIV) infection with subsequent development of HIV-associated salivary gland disease.
 - Opportunistic infections such as cytomegalovirus, adenovirus, cryptococcus, and histoplasmosis may secondarily infect the salivary glands of immunocompromised patients:
 - CMV sialadenitis may occur in the immune-competent patient, too.

Mumps (Fig. 19-19)

Definition: Self-limiting illness caused by an RNA virus in the Paramyxoviridae family that affects salivary glands.

Synonym: Epidemic parotitis

Clinical

- Acute illness of school-aged children and teenagers; uncommon in people 20 years of age and older
- Due to immunization programs that include measles, mumps, and rubella, mumps is uncommon in the United States.
- Highly contagious; transmitted by droplet spread of upper respiratory secretions
- After an incubation period of around 16 to 18 days, disease onset includes a prodrome of fever, headache, malaise, and nausea followed by painful, rapid swelling of one or both parotid glands over a 1- to 3-day period:
 - Pain is potentiated by foods that stimulate salivation, including citrus fruits or other sour liquids.

Fig. 19-19. Mumps.

This child had rapid and painful enlargement of both parotid glands over days.

- Other glands may be affected, including the lacrimal gland, thyroid gland.
- Systemic manifestations due to viremia may include:
 - Hepatosplenomegaly, pancreatitis, abdominal pain, lymphadenopathy, polyarthritides, (aseptic) meningitis, and encephalitis:
 - Systemic manifestations are more likely to occur in adults.
 - Orchitis and epididymitis can occur in approximately one third of postpubescent males.
 - Swelling and systemic symptoms gradually subside in 3 to 7 days.
- Diagnosis usually made on clinical grounds, which may include serum antibody titers and serum isoamylase fractions; surgical resection rarely occurs.
- Patients who are serologically negative for mumps may have infection caused by other viruses, including Coxsackie A, ECHO, Epstein-Barr virus, cytomegalovirus, parainfluenza virus type C, and lymphocytic choriomeningitis virus.

Pathology

- Histologic findings include presence of a marked lymphoplasmacytic cell infiltrate in periductal and periacinar tissues, as well as hemorrhage and necrosis.
- Viral inclusions are not identified.

Treatment and Prognosis

- Self-limiting infection and treatment is symptomatic.

Fig. 19-20. HIV salivary gland disease.

This HIV-infected patient has enlargement of his right parotid gland area, which represents the clinical presentation of HIV salivary gland disease. Note the scar of the left neck representing prior resection of an enlarged left parotid gland, which also shows HIV-related changes.

- Complications of infection are rare and include:
 - Sterility in men secondary to testicular atrophy after orchitis
 - Deafness as a sequelae to encephalitis
- Fatalities are rare and are related to encephalitis, myocarditis, and nephritis.

Human Immunodeficiency Virus Salivary Gland Disease (HIV-SGD) (Figs. 19-20 through 19-26)

Definition: HIV-SGD is defined as those HIV-infected individuals with xerostomia, enlargement of one or more major salivary glands, or both.

Synonyms: AIDS-related parotid cyst (ARPC); cystic lymphoid hyperplasia (CLH)

Clinical

- Include HIV-infected individuals with xerostomia, enlargement of one or more major salivary glands, or both of the above
- May represent the initial manifestations of HIV infection
- Exact incidence of salivary gland enlargement in HIV-infected individuals is not known but has been considered to be about 5% of adult patients.

Fig. 19-21. Imaging findings in HIV-SGD.

CT scan imaging in HIV-SGD showing the presence of bilateral, multicentric, variable-sized cysts.

- Primarily affects adult men aged 20 to 60 years with greater than 90% of cases occurring in men:
 - May occur in children born of HIV-infected mothers; under these circumstances there is no gender predilection
- Symptoms include painless swelling of one or more salivary glands, xerostomia, dry eyes, and arthralgias.
- Salivary gland involvement is almost always the parotid gland (98%) and less often the submandibular gland (2%):
 - In approximately 60% of the cases there is bilateral disease.
- Salivary gland involvement typically occurs in the early stages of HIV disease prior to the development of AIDS.
- Serology evaluation will confirm HIV positivity.
 - Serologic markers that are present in Sjögren syndrome, including polyclonal hypergammaglobulinemia and production of organ-specific autoantibodies (anti-salivary duct antibodies, autoantibodies), non-organ-specific (rheumatoid factor, Anti-Nuclear Antibodies [ANA], anti-RO [SS-A], anti-LA [SS-B]) are commonly absent in HIV-SGD.
- CT scan and MRI show unilateral or bilateral multicentric cysts of varying sizes.
- Sjögren syndrome-like illness has also been identified in AIDS patients, representing additional evidence of the severely damaged immune system in these patients.
- Diffuse infiltrative lymphocytosis syndrome (DILS) and HIV-associated CD8+ lymphocytosis syndrome:

Fig. 19-22. Cytology in HIV-SGD.

Fine-needle aspiration biopsy of HIV-SGD.

A, Heterogeneous lymphoid population is present, including the presence of scattered plasma cells, macrophages, and a multinucleated giant cell (*lower*).

B, Higher magnification showing the multinucleated giant cells. In the appropriate clinical setting, these cytologic findings would be consistent with HIV infection.

- Represents an uncommon manifestation of HIV infection characterized by persistent circulating CD8+ lymphocytosis accompanied by visceral lymphocytic infiltration
 - Primarily characterized by parotid gland enlargement, sicca symptoms, and pulmonary involvement occurs in HIV infection
 - Appears to be an antigen (viral)-driven response
 - Associated with CD8 lymphocytosis and the presence of HLA-DR5 and appears to be a genetically determined host immune response to HIV
 - In DILS, certain HIV-infected individuals develop oligoclonal expansion of CD8+ lymphocytes characterized by a persistent circulating CD8+ lymphocytosis.
 - These cells infiltrate multiple organs, but the salivary glands and the lung constitute the major sites of involvement.

Fig. 19-23. HIV-SGD.

A, B, Multiple epithelial-lined cysts with associated lymphoid cell proliferation, including florid follicular hyperplasia with attenuated to absent mantle lymphocytes.

Fig. 19-24. HIV-SGD.

In addition to the epithelial-lined cysts and the lymphoid changes, the histology of HIV-SGD also includes the presence of lymphoepithelial islands (identical to those seen in lymphoepithelial sialadenitis).

Fig. 19-25. HIV-SGD.

A, Findings include an epithelial lining infiltrated by mature lymphocytes (so-called lymphoepithelium) with a subjacent small lymphoid aggregate. **B,** Lymphoepithelial lesion (left of center) within the cyst wall. Such features in conjunction with other findings, the presence of multinucleated giant cells (right of center) would support the diagnostic consideration of HIV-SGD but requires clinical and serologic correlation.

- This infiltrative process resembles in many aspects a Sjögren-like syndrome, owing to the visceral lymphocytic infiltration.
- Pulmonary process associated with DILS may mimic clinically and radiographically the pneumonic process caused by *Pneumocystis jiroveci* (formerly *carinii*).
- Other manifestations of DILS to consider include a severe form of peripheral neuropathy, lymphocytic infiltration of the liver, evident as hepatitis, myositis, and lymphocytic interstitial nephritis.
- DILS may progress to development of parotid cysts.
- DILS in HIV has similarities to classic Sjögren syndrome, manifested by distinctive clinical, serologic, immunologic, and immunogenetic characteristics:

Fig. 19-26. p24 immunoreactivity.

Immunohistochemical staining against HIV p24 core antigen is confirmatory of HIV infection with reactivity (*left*) within the follicular dendritic cells of the germinal center and (*right*) multinucleated giant cells representing the reservoirs for the virus and/or antigen processing cells.

- In contrast to Sjögren syndrome, the greater degree of salivary gland enlargement and extraglandular disease, including pulmonary, renal, gastrointestinal, breast, and muscle, as well as the low frequency of autoantibodies and differing HLA associations seen in DILS, serve to distinguish DILS from classic Sjögren syndrome.
- Primary treatment anti-HIV therapy

Pathology

Cytology (Fine-Needle Aspiration Biopsy [FNAB])

- Simple and cost-effective procedure for the diagnosis
- Diagnosis of HIV-SGD can be considered in cystic parotid gland lesion(s) showing a combination of:
 - Heterogeneous lymphoid population
 - Scattered single and/or clustered foamy macrophages
 - Numerous multinucleated giant cells
 - Superficial and/or anucleated squamous cells

Histology

Lymphoid-Related Changes

- Histologic alterations similar to changes seen in lymph nodes in early phases of HIV infection, including florid follicular hyperplasia, attenuated to absent mantle lymphocytes, disruption of the germinal centers (follicle lysis), and the presence of multinucleated giant cells (MGCs) localized to interfollicular, intrafollicular, and periepithelial areas
- Monomorphic round cells with clear cytoplasm (monocytoid B-cells) can be found in clusters.

- Interfollicular mixed (benign) inflammatory-cell infiltrate with mature lymphocytes, histiocytes, neutrophils, and plasma cells are also present.

Cystic Changes

- In addition to the lymphoid changes, multiple squamous epithelial-lined cysts and lymphoepithelial lesions are present.
- Squamous epithelial-lined cysts and the lymphoepithelial lesions typically permeated by mature lymphocytes (typically monocytoid B-cells in epimyoeplithelial islands)
- Lymphoepithelial lesions formed by hyperplasia and metaplasia of ductal epithelium
- Origin of cysts appears to be from the salivary gland (parotid) epithelial structures arising in intraparotid or periparotid lymph nodes accounting for the lymphoid component:
 - Similar cysts can be found in HIV-negative patients.
- Presence of HIV-1 suggests pathogenesis of salivary gland lymphoepithelial lesions is primarily due to this virus.
- Histochemistry:
 - For the lymphoid changes and the cystic lesions, special stains for microorganisms are negative.
- Immunohistochemistry:
 - Presence of B-cell lineage (e.g., CD20, others) and T-cell lineage markers (CD3, others)
 - Epithelial markers (cytokeratins, others) delineate squamous epithelial-lined cysts and epimyoeplithelial islands.
 - Immunoreactivity with HIV p24 core antigen can be found in the germinal centers (follicular dendritic cells), scattered lymphoid cells and in the multinucleated giant cells:
 - Multinucleated giant cells may also show the presence of S100 protein and p55 (actin bundling protein).
- Cytogenetics and molecular genetics:
 - In two related settings, diffuse infiltrative lymphocytosis syndrome (DILS) and HIV-associated CD8+ lymphocytosis syndrome, monoclonal TCR gene has been reported:
 - Despite the finding of monoclonal TCR gene, there is evidence that the CD8+ expansions are reactive populations capable of mediating non-cytotoxic inhibition of HIV replication that is believed to represent an immune response to viral infection rather than a malignant disorder.

Differential Diagnosis

- Other infectious diseases
- Salivary gland lesions with morphologic changes that overlap with HIV-SGD collectively referred to

as lymphoepithelial lesion (LEL) occurring in lymphoepithelial sialadenitis (see later).

- Sjögren syndrome:
 - Serologic markers that are present in Sjögren syndrome, including polyclonal hypergammaglobulinemia and production of organ-specific autoantibodies (antisalivary duct antibodies autoantibodies), non-organ-specific (rheumatoid factor, anti-nuclear antibodies [ANA], anti-RO [SS-A], anti-LA [SS-B]) are commonly absent in HIV-SGD.
- Cystic salivary gland neoplasms:
 - In general, differentiation from salivary gland neoplasms (benign and malignant) is straightforward because the cellular components that are diagnostic for a given salivary gland neoplasm are absent in HIV-SGD.
- Malignant lymphomas:
 - Differentiation from malignant lymphoma is predicated on the presence of a heterogeneous cell population and correlating IHC reactivity for B- and T-cells, as well as the absence of a monomorphic cell population, absence of cytologically malignant cells, and absence of clonal cell population by immunohistochemical and/or molecular diagnostic modes of evaluation.

Treatment and Prognosis

- Treatment for HIV-SGD varies and includes surgical resection (parotidectomy, conservative excision, curettage), radiation, and symptomatic relief.
- Highly active antiretroviral treatment (HAART) has been shown to reduce the size of parotid swellings and even result in regression of HIV-SGD:
 - Successful outcome reflected in diminution of viral load and to some degree of immune restoration.
 - Parotid gland involvement does not appear to play any role in the course of the disease or progression to AIDS.
- Prevalence of DILS had significantly decreased in the post-HAART era, suggesting that DILS is an antigen (viral)-driven response and the primary treatment for it is anti-HIV therapy.
- HIV-SGD is benign but hematologic malignancies may occur in association with the HIV-SGD or develop subsequently:
 - Polymorphic B-cell lymphoproliferative disorders comparable morphologically and molecularly to those arising after solid organ transplantation also occur in association with HIV infection, although their biologic significance and malignant status remains unclear.

Chronic Sialadenitis

Definition: Chronic inflammation of salivary glands that may result from a variety of causes, including nonobstructive diseases and obstructive lesions.

- Causes include:
 - Mechanical obstruction, infectious disease, and autoimmune diseases
 - In many patients the cause of chronic sialadenitis is less clear and is due to a category of lesions referred to as chronic recurrent sialadenitis.

Chronic Nonobstructive Sialadenitis

- Chronic nonobstructive sialadenitis may have specific causes, including granulomatous sialadenitis (infectious and noninfectious) or irradiation.
- Sialadenitis secondary to radioactive iodine therapy for thyroid carcinoma is common.
- Granulomatous inflammation of the salivary glands most often is caused by duct obstruction (e.g., calculi, carcinoma), resulting in extravasation of the obstructed duct content into the salivary gland parenchyma causing a foreign body granulomatous inflammatory reaction.
- Granulomatous sialadenitis due to an infectious cause is less common and is caused by a number of diseases including (but not limited to) tuberculosis, actinomycosis, and cat-scratch disease.
- Sarcoidosis is yet another cause of granulomatous sialadenitis associated with chronic nonobstructive sialadenitis (see later).
- Granulomatous sialadenitis may occur as an isolated phenomenon but is more commonly seen as part of a systemic process; such a phenomenon may be seen in association with sarcoidosis, cystic fibrosis, and Crohn disease.

Sarcoidosis of Salivary Glands (Fig. 19-27)

Definition: Sarcoidosis is a multisystem chronic (noncaseating) granulomatous disease of unknown cause that affects a variety of sites, including (but not limited to) lymph nodes, lungs, mucosal sites of the upper aerodigestive tract, salivary glands, skin, spleen, and liver.

Synonym: Boeck disease

Clinical

- Worldwide sarcoidosis is most common in young to middle-aged women.
- In the United States, sarcoidosis is ten times more common in African Americans with a female

Fig. 19-27. Sarcoidosis.

Sarcoidosis in the parotid gland. Intraparenchymal noncaseating granulomas are identified. Special stains for microorganisms were negative. The patient was known to have sarcoidosis.

predominance; there is a higher prevalence among people in the southeast United States.

- Pulmonary symptoms are present in approximately 60% of cases and consist of dyspnea, cough, and nonpleuritic chest pain.
- Nonspecific symptoms may include fever, malaise, weight loss, and lymphadenopathy, the latter including (but not limited to) hilar and paratracheal lymph nodes.
- Cutaneous lesions may occur in up to one third of patients and red- or purple-appearing papules.
- In head and neck, more common sites of involvement include:
 - Cervical neck lymph nodes (anterior and posterior cervical lymph nodes), eye, salivary glands, and mucosal sites of the upper aerodigestive tract
 - Salivary gland involvement usually includes the parotid gland and submandibular gland, but minor salivary glands may be affected.
- Parotid gland involvement may occur as an isolated process or as part of a syndrome termed uveoparotid fever, also known as Heerfordt syndrome, characterized by the parotitis, xerostomia, uveitis, and facial nerve palsy.
 - Parotid gland sarcoidosis:
 - Occurs in 6% of patients with systemic sarcoidosis and may be bilateral in a majority of cases
 - May occur in association with Sjögren disease
 - May present with sicca complex (xerophthalmia and xerostomia), suggesting a clinical

diagnosis of Sjögren syndrome (see Differential Diagnosis later)

- No laboratory findings specific for or diagnostic of sarcoidosis:
 - Elevated serum levels of angiotensin-converting enzyme (ACE) are found in patients with active pulmonary sarcoidosis; however, ACE levels are elevated in other (nonsarcoid) diseases including liver disease and leprosy.
 - Cutaneous anergy to skin test (“sarcoid”) antigens referred to as the Kveim test is positive in a majority of patients with recently diagnosed (sub-acute) sarcoidosis; the Kveim test reaction may be low or absent in patients with inactive or chronic sarcoidosis.
- Although a known cause has not been elucidated to date, speculation remains that sarcoidosis is an infectious disease possibly caused by a mycobacterial infection (i.e., mycobacteria other than *M. tuberculosis* [MOTT]).

Pathology

Cytology

- Collections of epithelioid histiocytes with or without multinucleated giant cells without accompanying necrosis or acute inflammation
- Salivary gland acini with varying degrees of degenerative changes
- Efficacy, utility, and cost savings of fine-needle aspiration biopsy in the diagnosis and differential diagnosis of granulomatous sialadenitis to include sarcoidosis has been demonstrated in numerous studies.

Microscopic

- Histologic hallmark is presence of well-formed, noncaseating granulomas consisting of epithelioid histiocytes surrounded by a mixed inflammatory infiltrate and multinucleated (Langhans type) giant cells.
- Intracytoplasmic inclusions including star-shaped, referred to as asteroid bodies, and calcific laminated bodies, called Schaumann bodies, can be seen.
- No polarizable, pigmented foreign material or dissolvable material is identified.
- Histochemistry:
 - All special stains for microorganisms, including Gomori methenamine silver (GMS) and acid-fast bacilli (AFB), are negative.

Differential Diagnosis

NOTE: The noncaseating granulomas of sarcoidosis are not pathognomonic. The pathologic features of sarcoidosis are characteristic but they are not specific; the diagnosis of sarcoidosis can only be considered in the absence of identifying an infectious agent.

- Other granulomatous disease, primarily of infectious cause, such as mycobacterial infection and fungal infection:
 - Identification of microorganisms by special stains, microbiologic cultures, and/or molecular analysis allows for differentiation.
- Noncaseating granulomas unrelated to an infectious cause can be seen in association with rheumatoid arthritis (rheumatoid nodule) and as a reactive process in tissues (e.g., lymph nodes) adjacent to malignancies; detailed clinical history should allow for differentiating these lesions from sarcoidosis.
- Sjögren syndrome:
 - Patients with sarcoidosis of the salivary glands may present with sicca complex (xerophthalmia and xerostomia) suggesting a clinical diagnosis of Sjögren syndrome (SS):
 - In contrast to patients with sarcoidosis, patients with SS present more frequently with Raynaud phenomenon, more often have autoantibodies, and minor salivary gland biopsy (MSGB) shows focal sialadenitis in the majority of the patients.
 - Patients with sarcoidosis more frequently have parotid gland enlargement, mainly have pulmonary and cutaneous involvement, lack autoantibodies, and histopathologic findings of MSGB may show noncaseating granulomas.
 - In cases in which there are equivocal findings by MSGB, transbronchial lung biopsy may be required and the presence of noncaseating granulomas is diagnostic of sarcoidosis.
- For a more complete discussion, including histopathologic features and illustrations, see Section 1, Sino-nasal Tract.
- Often a nodal-based proliferation occurring as part of a generalized process involving lymph nodes; SHML involve extranodal sites independent of the lymph node status
- Head and neck region represents one of the more common extranodal areas affected by SHML:
 - Within the head and neck, there is predilection for the nasal cavity and paranasal sinuses.
 - Virtually all head and neck sites may be affected in association with or independent of nodal disease, including major salivary glands.
 - Salivary gland involvement is uncommon and may occur in association with other extranodal head and neck sites involved by SHML or occurs independent of other sites of involvement.
- Salivary gland involvement:
 - No gender predilection
 - Occurs over a wide age range
- Parotid gland and submandibular glands are most often affected; lacrimal glands may also be involved.
- Patients with salivary gland involvement present with a discrete, painless mass, which clinically may suggest a primary salivary gland tumor.
- SHML may occur in association with HIV-infected patients, Sjögren syndrome, and amyloidosis; SHML co-existing with Langerhans cell histiocytosis has also been reported.
- Salivary gland lesions are polypoid, nodular, or exophytic growths with a tan-white to yellow appearance.
- No ideal treatment:
 - Treatment protocols should mirror the clinical manifestations such that a range of therapeutic modalities may be used.
- Transformation to a high-grade lymphoma may rarely occur.

Treatment and Prognosis

- Clinical course in the majority of patients is benign, and spontaneous remission may occur within 2 years of the diagnosis.
- Treatment for systemic sarcoidosis in which there is extensive disease or disease that compromises normal function can be by corticosteroid therapy.
- Prognosis for systemic disease is generally good, with up to 70% of patients improving or remaining stable after therapy.
- Advanced multisystem disease leading to extensive pulmonary involvement and respiratory failure may occur but is seen in only a small percentage of cases.
- Less than 10% of patients die of pulmonary, cardiac, or central nervous system involvement.

Extranodal Sinus Histiocytosis with Massive Lymphadenopathy

- Idiopathic, histiocytic proliferative disorder that usually resolves spontaneously
Synonyms: Rosai-Dorfman disease, Destombes-Rosai-Dorfman syndrome

Chronic Obstructive Sialadenitis

- Most common cause of obstructive or occlusive sialadenitis is stone formation referred to as sialolithiasis (see later); less common causes of chronic obstructive sialadenitis include:
 - Stenosis, stricture
 - Congenital duct malformations
 - Ascending infections
 - Kussmaul disease (fibromucinous plugs in the collecting system of dehydrated patients)
 - Trauma
- In children, mumps (see earlier) is a common cause of sialadenitis; less common, children may also suffer from recurrent parotitis, the cause of which remains uncertain, characterized by:

Fig. 19-28. Sialolithiasis.

Oral cavity showing a white stone situated within the orifice of the parotid (Stensen) duct causing an obstructive sialadenitis.

- Recurrent, acute exacerbations of inflammation resulting in a slowly progressive destruction of the parotid gland.
- Chronic sialadenitis may or may not be associated with stone formation; however, calculi are seen in nearly two thirds of patients with chronic sialadenitis.
- Chronic sialadenitis more commonly affects the parotid gland, probably resulting from the anatomy of Stenson duct, which is long and narrow making it more susceptible to any alterations in the composition of its saliva.

Sialolithiasis (Figs. 19-28 through 19-31)

Definition: Occurrence of calcereous concretions within salivary gland ducts and/or parenchyma as a result of mineralization of debris accumulated within duct lumens.

Clinical

- Calculi may be seen in the ductal system of all salivary glands but are particularly common in the submandibular gland (Wharton duct), accounting for 80% to 90% of cases, and parotid gland (Stensen duct), accounting for 10% to 20% of cases:
 - Greater involvement of the submandibular gland is thought to be due to the higher mucin content of its saliva with more adherent properties.
 - Sublingual or minor salivary glands are rarely affected.
 - Involvement of minor salivary glands usually includes the upper lip and buccal mucosa.

Fig. 19-29. Sialolithiasis.

A, A calculus is seen within a large duct as concentric laminations of calcification peripherally surrounded by compressed ductal epithelium and fibrotic change within adjacent salivary gland parenchyma; minimal inflammation is present. **B,** In this example a calculus is present within a duct surrounded by the presence of a marked inflammatory cell infiltrate.

- Salivary calculi occur slightly more often in men than in women; occur at any age but are most frequently seen in middle-aged adults; pediatric sialolithiasis is uncommon.
- Symptoms depend on size and location of calculi:
 - Submandibular gland calculi are:
 - Larger than those of the parotid gland, producing recurrent episodes of pain and swelling usually in association with meals
 - May be associated with sore throat or pharyngitis refractory to antibiotic therapy
 - Parotid gland calculi are:
 - Usually smaller than those of the submandibular gland
 - May function as a ball-valve effect, producing intermittent obstruction and symptoms; the latter include pain and swelling

Fig. 19-30. Sialolithiasis.

A and B, Ectatic duct filled with reddish-appearing crystalline stone material with associated neutrophils and blue-appearing bacterial colonization; cyst epithelial lining is attenuated and includes scattered cells with enlarged hyperchromatic nuclei (*arrowheads*). The wall of the cyst shows fibrosis and scattered fibroblasts. The cyst lining may variably include (**C**) oncocytic cells; (**D**) squamous cells. Mucous cells may be present (not shown). **C, D,** In some cases there may be extracellular mucus extravasation (in cyst wall) that, in conjunction with squamous-appearing cells and mucocytes, may suggest a diagnosis of mucoepidermoid carcinoma (MEC). The absence of a proliferative (thickened) epithelial component, including an admixture of epidermoid cells, mucocytes, and intermediate cells as well as presence of identifiable intraductal stone material, would weigh against a diagnosis of MEC.

- If obstruction is not relieved, stasis of saliva ensues, potentially resulting in an associated bacterial infection (most often due to *Streptococcus viridans*), manifested by expression from the ducts of mucopurulent material (pus).
- Calculi may be palpated or even visualized in the distal duct system; because of its deeper anatomic location, calculi within Stenson duct are often not palpable.
- Calculi are formed by deposition of calcium phosphate and an organic matrix made up of various amino acids and carbohydrates around a central nidus thought to be either bacteria or inorganic material; stone development has no correlation to the serum calcium or phosphorus levels.
- Radiographic analysis represents the most reliable means to detect the presence of calculi:
 - Majority of calculi are radiopaque and can be visualized by routine radiography.
 - Majority of parotid gland calculi are radiolucent and may require special oblique views of the cheek for visualization.
 - Sialography may be of assistance but is often unnecessary, yielding limited additional information and being a potential source of inducing an infection.

Fig. 19-31. Sialolithiasis.

A, B, Over time, the surrounding parenchymal changes in sialolithiasis may include fibrosis, parenchymal atrophy with loss of acini, chronic inflammation, and scarring.

- Cause:
 - Remains uncertain
 - Suggested correlation with smoking history, diuretic use

Pathology

Gross

- Affected gland is enlarged, firm, and nonfluctuating.
- Sialoliths are round to oval, white to yellow-brown, measuring from a few millimeters to several centimeters in diameter.

Cytology

- Abundant polyhedral, multifaceted (nontyrosine) crystalloids may be seen in the background of scanty cellular specimens composed predominantly of oncocytic cells.

- When crystalloids/stone fragments identified in aspirated material, these cases pose little diagnostic difficulty.
- When crystalloids/stone fragments not present, epithelial changes and mucus accumulation may be difficult to distinguish from low-grade mucoepidermoid carcinoma or other neoplasms.

Histology

- Calculi may be seen within the parenchyma or in the ducts as concentric laminations of calcification peripherally surrounded by compressed epithelium.
- Ductal epithelium may demonstrate mucous cell, squamous, or oncocytic metaplasia.
- With chronicity of disease, parenchymal changes may include fibrosis, parenchymal atrophy with loss of acini, chronic inflammation, ductal dilatation, and scarring.

Treatment and Prognosis

- Small stones can be treated conservatively by increased intake of fluids, moist heat, analgesics, and massage; such therapy may result in the passage of the stone with restoration of salivary flow; calculi may pass spontaneously.
- Failure by conservative means or if the stone is large necessitates surgical removal of the obstruction, which varies from excisional biopsy to shock wave lithotripsy to removal of the entire submandibular or parotid gland.
- Antibiotics are administered in those cases secondarily infected. Recurrent infections may occur if the cause of the obstruction is not removed.

Chronic Recurrent Sialadenitis (Fig. 19-32)

Definition: Represents a group of lesions primarily affecting the parotid gland characterized by recurrent attacks of swelling associated with pain involving one or both glands.

Clinical

- No gender predilection; may affect children or adults
- Clinically, characterized by recurrent attacks of swelling of affected gland with associated pain
- Primarily involves parotid gland
 - One or both parotid glands may be affected
 - Anatomically, parotid gland duct (Stensen duct) is long and narrow as compared with the shorter and wider submandibular gland duct (Wharton duct), predisposing parotid gland to abnormalities of secretions that may result in recurrent sialadenitis.

Fig. 19-32. Chronic recurrent sialadenitis.

A, B, Duct ectasia with retention of the lobular architecture of the gland; a mild inflammatory cell infiltrate (composed of mature lymphocytes and plasma cells) is present within the parenchyma.

- Cause:
 - Remains uncertain but predisposing factors associated with alterations of saliva (decreased secretion, stasis, and changes in its chemical composition) creating an environment conducive for infection with induction of ductal epithelial metaplasia resulting in obstruction and recurrent inflammation(s)
- Sialography remains the preferred investigation.
- Diagnostic sialadenoscopy may complement or even supersede sialography as the diagnostic procedure of choice, but at present more experience is needed in this technique and its use becomes more widespread.

Pathology

Histology

- In the initial stages the regular lobular architecture of the gland is retained.
- Duct ectasia surrounded by a mild inflammatory cell component composed of mature lymphocytes and plasma cells is present.

- Advanced stages characterized by a marked increase of periductal inflammatory cell infiltrate eventually resulting in near complete obliteration of the affected gland with destruction of the lobular formation and effacement of the salivary gland parenchyma.
- Lymphoid follicles may be present and in some cases lymphoepithelial islands similar in appearance to those identified in benign lymphoepithelial lesions may be present.

Treatment and Prognosis

- May spontaneously resolve with puberty; however, spontaneous resolution in the adult population is not common
- Because cause and pathogenesis remains unknown, no causal therapy is available.
- Therapy may vary from conservative treatment to surgery and a variety of therapeutic modalities have been used, including gland massage, infrared light, antibiotics, injection of a sclerosing agent (e.g., methyl violet), antiphlogistics, Trasyolol, duct occlusion, ductal ligation, ductoplasty, gland denervation, tympanic neurectomy, and radiotherapy.
- Conservative management often fails necessitating surgery (e.g., parotidectomy):
 - For patients unresponsive to conservative measures, superficial parotidectomy with preservation of the main duct is safe and effective in the treatment of chronic sialadenitis, and in some patients allows for some preservation of function.

Sialadenosis

Definition: Non-neoplastic, noninflammatory enlargement of salivary glands (in particular parotid), which is almost always associated with an underlying systemic disorder or a secretory dysfunction.

Synonym: Sialosis

Clinical

- No gender predilection; occurs most commonly in adults
- Salivary gland enlargement most often affects parotid gland:
 - Is usually bilateral
 - Is an indolent process
 - May be chronic and recurrent
 - May be associated with pain
- Almost always associated with a systemic disorder, including:
 - Diabetes, thyroid insufficiency, alcoholism, malnutrition, hepatic cirrhosis, drug reactions (e.g., antihypertensive medications), anorexia nervosa, and bulimia
 - Patients are generally afebrile.

- Pathogenesis:
 - Major loss and thinning of myofilament component of myoepithelial cells, resulting in loss of mechanical support for the acini, proposed as causative of sialadenosis:
 - Allows acinar cells to expand as secretory granules accumulate intracellularly to produce great acinar enlargement
 - Functional myoepithelial insufficiency is possibly a consequence of an autonomic neuropathy secondary to severe metabolic or hormonal disorders.

Pathology

Cytology

- Smears show clusters of swollen acini and numerous naked nuclei of acinar origin in the background and an absence of inflammatory cells.
 - Features are considered distinctive enough to enable its diagnosis on fine-needle aspiration.

Histology

- Acinar cell enlargement with absent inflammatory cell infiltrate.
 - Acinar cell enlargement may take the form of a granular-appearing cytoplasm with densely packed periodic acid Schiff positive material or honeycomb with vacuolated-appearing cytoplasm or both.
- Histologic findings demonstrate little correlation to specific underlying disorder.
- As disease persists, atrophy of parenchymal tissues are seen but the glands remain enlarged due to compensatory increase in intraglandular adipose tissue.

Differential Diagnosis

- Inflammatory and infectious disease of salivary glands:
 - A careful and detailed history should allow for the diagnosis and differentiating sialadenosis from other lesions.

Treatment and Prognosis

- Treatment directed toward treating the underlying systemic disorder
- Patients with sialadenosis secondary to systemic endocrine disorders, hepatic cirrhosis, or neurogenic abnormalities tend to be resistant to treatment.

IgG4-Related Diseases (IgG4-RD)

Definition: Multiorgan autoimmune disorder that can affect any organ, has heterogenous presentation, and is characterized by fibrous inflammation, IgG4-positive

plasma cell infiltration in affected tissues, and elevated serum concentrations of IgG4.

- Diagnosis of IgG4-RD unifies many eponymous fibroinflammatory conditions previously thought to be confined to single organs.
- Consensus on pathologic criteria for diagnosis in specific organs include:
 - Tendency to form tumefactive lesions in multiple sites
 - Characteristic histopathologic appearance, including:
 - Dense lymphoplasmacytic infiltrate
 - Storiform pattern of fibrosis
 - Obliterative phlebitis
 - Increased numbers of IgG4⁺ plasma cell
 - Often but not always elevated serum IgG4 concentrations
 - Tissue IgG4 counts and IgG4:IgG ratios are secondary in importance.
 - Pathologic findings do not supplant careful clinicopathologic correlation and sound clinical judgment.
- Recognition and diagnosis of IgG4-RD crucial owing to the fact that there is a favorable response to immunosuppression (e.g., glucocorticoids, rituximab)
- Precise mechanisms leading to disease are unknown.
- Characteristically IgG4-RD affects the pancreas, referred to as autoimmune pancreatitis (AIP), which consists of two distinct pathologic entities:
 - Type 1 AIP:
 - Manifestation of a systemic IgG4-related disease
 - Affects older patients
 - Characterized by an elevated serum IgG4 level and sites of extra-pancreatic disease
 - Characteristic features include:
 - Increased serum IgG4 levels
 - Lymphoplasmacytic sclerosing pancreatitis including:
 - Abundant infiltration of IgG4⁺ plasmacytes and lymphocytes
 - Storiform fibrosis
 - Obliterative phlebitis
 - Extra-pancreatic manifestations (e.g., sclerosing cholangitis, sclerosing sialadenitis, retroperitoneal fibrosis, others)
 - Steroid responsiveness
 - Type 2 AIP
 - Not associated with elevated IgG4 levels or extra-pancreatic disease
 - Disease process confined to the pancreas
 - Affects younger patients
 - Associated with inflammatory bowel disease
 - Both subtypes can mimic malignancy, particularly pancreatic cancer.

- Possible pathogenesis:
 - IgG4-RD lesions infiltrated by T helper cells, which likely cause progressive fibrosis and organ damage
 - IgG4 antibodies are generally regarded as noninflammatory:
 - Autoreactive IgG4 antibodies are observed in IgG4-RD but there is no evidence that they are directly pathogenic.
 - Rituximab-induced B-cell depletion in IgG4-RD leads to rapid clinical and histologic improvement accompanied by swift declines in serum IgG4 concentrations.
 - Although IgG autoantibodies against various exocrine gland antigens have been described, in IgG4-RD remains unknown whether they are members of IgG4 subclass
 - Contribution of autoantibodies to IgG4-RD remains unclear.
- After the pancreatobiliary system, head and neck is next most common site for involvement by IgG4-related disease.
- Head and neck manifestations of IgG4-RD include involvement of:
 - Salivary gland(s)
 - IgG4-related sialadenitis, see later.
 - Mikulicz disease, see later.
 - Sclerosing mucoepidermoid carcinoma, see Chapter 20:
 - Suggested relationship to IgG4-RD but has not definitively been proven
 - Thyroid gland (see Section 8):
 - Conflicting information in the literature whether the fibrous variant of Hashimoto thyroiditis represents an IgG4-RD
 - Reidel thyroiditis
 - Sclerosing mucoepidermoid carcinoma:
 - Suggested relationship to IgG4-RD but has not definitively been proven
 - Sinonasal tract:
 - Eosinophilic angiocentric fibrosis
 - Other head and neck sites of involvement may include (but not necessarily limited to):
 - Ear, soft tissue, lymph nodes
 - Lacrimal gland

IgG4-Related Sialadenitis

(Figs. 19-33 and 19-34)

Definition: Chronic fibroinflammatory salivary gland disease with characteristic morphology included within the spectrum of systemic IgG4-related diseases that includes autoimmune pancreatitis and involvement of extrapancreatic organs (e.g., kidney, lung, retroperitoneum, liver, gallbladder, lymph nodes, breast, salivary glands, lacrimal glands, aorta).

- IgG4-related sialadenitis may include:
 - Chronic sclerosing sialadenitis (CSS):
 - Synonyms: Küttner tumor, punctate parotitis
 - Mikulicz disease (MD):
 - Was considered to be subtype of Sjögren syndrome (SS) based on histopathologic similarities
 - Recent studies indicated that patients with MD show high serum IgG4 concentration
 - MD considered as an IgG4-related disease distinguishable from SS
- To establish a definitive diagnosis of IgG4-related sialadenitis in the clinical and pathologic settings that correlate to CSS and MD, immunohistochemical staining should be performed to determine the number and fraction of plasma cells with IgG4:
 - Not all cases of CSS (Küttner tumor) and MD show requisite IgG4 to IgG plasma cells to establish a definitive diagnosis of IgG4-related sialadenitis.

Clinical

- Incidence of IgG4-associated sialadenitis unknown
- More common in men than in women; usually occurs from the fourth to seventh decades of life
- Primarily involves submandibular gland:
 - Typically one gland
 - Rarely multiple glands (major and minor) may be affected in a single patient
 - In Mikulicz disease (MD), in addition to salivary gland involvement, there is persistent swelling of lacrimal glands
- Symptoms include pain and swelling often associated with ingestion of food
 - Patients may present with asymptomatic swelling of affected gland.
- Disease process may be localized to salivary glands or may be associated with sclerosing lesions in extrasalivary gland tissues (i.e., systemic IgG4-related disease)
- Laboratory findings:
 - Elevated serum levels of IgG4, IgG, IgG4/IgG
 - Antibodies associated with Sjögren syndrome (e.g., anti-SSA, anti-SSB) are absent in IgG4-associated sialadenitis.
 - Serum ANCA and proteinase 3 levels are not elevated.
 - Eosinophilia, hypergammaglobulinemia, and antinuclear antibodies (ANA) may be present in systemic disease but are not typically elevated in localized disease.

Pathology

Cytology

- In combination with the clinical findings, the fine-needle aspiration biopsy (FNAB) findings can

Fig. 19-33. IgG4-related sialadenitis.

IgG4-related sialadenitis of the submandibular gland. Two different cases showing varying degree of fibrosis, creating a lobular appearance including (A) storiform type and (B) nonstoriform type; irregular-shaped germinal centers are evident. Storiform-type fibrosis is less common in relationship to salivary (submandibular) glands; (C) lobular architecture is preserved with lobules separated by fibrosis; acinar atrophy is evident; (D) dense lymphoplasmacytic infiltrate within lobules and extended into fibrosis; a prominent germinal center is present; (E) sheets of mature plasma cells.

Fig. 19-34. IgG4-related sialadenitis.

Immunohistochemical staining of the plasma cells includes (A) IgG4+ plasma cells and (B) IgG+ plasma cells. There is an IgG4+/IgG+ plasma cell ratio of >40% that in conjunction with the light microscopic pathologic findings is confirmatory of the diagnosis of IgG4-related sialadenitis.

strongly suggest the diagnosis of CSS and obviate the need of surgical intervention.

- FNAB findings include paucicellular to moderately cellular aspirate characterized by the presence of scattered tubular ductal structures often enveloped by collagen bundles or lymphoplasmacytic infiltrate, isolated fragments of fibrous stroma, a background rich in lymphoid cells, and paucity or absence of acini.

Gross

- Well-defined to circumscribed lesion involving a variable proportion of affected gland or may involve entire affected gland

Histology

- Histopathologic features of IgG4-related sialadenitis include:
 - Preservation of lobular architecture
 - Lobules separated by fibrosis:
 - Typical storiform-type fibrosis seen in other organs (e.g., pancreas) may not be as frequently present in salivary glands
 - Dense lymphoplasmacytic infiltrate within lobules and extended into fibrosis
 - Large, irregular lymphoid follicles with expanded germinal centers (florid lymphoid hyperplasia)
 - Sheets of mature plasma cells
 - Acinar atrophy
 - Obliterative phlebitis may or may not be present:
 - Venous channels are obliterated by dense lymphoplasmacytic infiltrate
 - Not as frequently seen as in other organ sites (e.g., pancreas)
 - Not required for diagnosis
 - Elastic stains may assist in confirming presence of phlebitis.
- Additional findings may include:
 - Squamous metaplasia of ducts
 - Mucous metaplasia of ducts
 - May include ciliated cells and goblet cells
 - Noncaseating granulomas may be seen:
 - Likely results from mucus extravasation from ducts in association with sialolithiasis
- Immunohistochemistry:
 - IgG4 immunostaining essential test for pathological diagnosis of IgG4-related disease:
 - Particularly applies to cases without elevated concentration of serum IgG4
 - Strongly recommended even in straightforward cases as it is a simple, highly reproducible test that provides strong confirmatory evidence for the diagnosis.
 - Appropriate cutoff number of IgG4+ plasma cells varies per organ and for salivary and lacrimal glands >100 per high-power field in conjunction with light microscopic features considered highly suggestive for diagnosis
 - Abundant IgG4-bearing plasma cells virtually always present in inflamed lobules, interlobular septae, and occasionally in germinal centers
 - IgG4+ plasma cell count alone may not help to distinguish between IgG4-related disease and disorders that are not part of that disease spectrum:
 - Some inflammatory lesions not IgG4-related disease associated with high numbers of IgG4+ plasma cells per high power field (HPF) owing to abundance of plasma cells

- IgG4+/IgG+ plasma cell ratio more powerful tool than IgG4+ plasma cell counts in establishing diagnosis:
 - IgG4+/IgG+ plasma cell ratio on immunostaining widely used to assess preferential shift to IgG4 production in affected sites
 - An IgG4+/IgG+ plasma cell ratio of >40% considered cutoff value in any organ
 - In absence of other corroborative findings, a IgG4+/IgG+ plasma cell ratio of >40% in and of itself is not considered sufficient pathologic evidence of IgG4-related disease:
 - Applies particularly to cases with low overall IgG4 count per HPF, in which there may be a shift of >40% but pathologic diagnosis of IgG4-related disease is untenable in absence of classic histopathologic features and a compatible clinical picture.
 - A variety of non-IgG4-related disease entities can have IgG4+/IgG+ plasma cell ratios of >40% including conditions sometimes associated with elevated serum interleukin-6 (IL-6) concentrations (e.g., multicentric Castleman disease, rheumatoid arthritis and other immune-mediated conditions sometimes occur with abundant IgG4+ plasma cells within tissue [IgG4+/IgG+ plasma cell ratio >40%] and elevated serum IgG4 concentrations)
- Plasma cells:
 - CD138 positive
 - Polytypic kappa and lambda light chain by immunohistochemistry and/or in situ hybridization
- Additional findings:
 - CD3+ interfollicular T-cells present especially in association with ducts and acini
 - CD20+ B-cells mostly restricted to lymphoid follicles
 - Follicles express bcl6 and negative for bcl2
- Cytogenetics and molecular genetics
 - Immunoglobulin heavy chain includes polyclonal rearrangement in the majority of cases.

Differential Diagnosis

- Chronic sialadenitis, not otherwise specified
- Sialolithiasis
- Sjögren syndrome
- Lymphoepithelial sialadenitis (LESA)
- Sarcoidosis
- Malignant lymphoma

Treatment and Prognosis

- Excellent response to immunosuppression (e.g., glucocorticoids, rituximab):

- Rituximab-induced B-cell depletion in IgG4-RD leads to rapid clinical and histologic improvement accompanied by swift declines in serum IgG4 concentrations.
- Rarely, extranodal marginal zone B-cell lymphoma (MALT) of salivary gland and salivary duct carcinoma develop in background of IgG4 sialadenitis.

Lymphoepithelial Sialadenitis (LESA) (Figs. 19-35 through 19-37)

Definition: Non-neoplastic unilateral or bilateral enlargement of major or minor salivary glands, and/or lacrimal glands associated with or occurring independent of an autoimmune disease, and characterized by specific histopathologic findings.

Synonyms: Benign lymphoepithelial lesions (BLEL); myoepithelial sialadenitis (MESA); immune sialadenitis; Godwin tumor; Godwin lesion

Introduction

- Designation of benign lymphoepithelial lesion (BLEL) initially coined in 1933
- Distinctive morphologic changes associated with BLEL have been referred to by a variety of terms and clinical settings
- Morphologic changes include the presence of lymphoepithelial islands or lesions:
 - Previously referred to as epimyoeplithelial islands
 - Believed to be composed of ductal and myoepithelial cells resulting in replacement of the term BLEL with myoepithelial sialadenitis (MESA)
 - Myoepithelial component has not been affirmed; hence the change in terminology to lymphoepithelial sialadenitis (LESA) and for the characteristic cell islands to be called lymphoepithelial islands or lesions.
- Morphologic changes of LESAs are distinctive but not pathognomonic and may be identified in a variety of salivary gland non-neoplastic and neoplastic lesions (Box 19-2), arguably most common in Sjögren syndrome

BOX 19-2 Occurrence of Lymphoepithelial Lesions in Salivary Gland Diseases

- Sialolithiasis
- Sialadenitis (infectious and noninfectious)
- Lymphoepithelial sialadenitis (LESA)
- Sjögren syndrome and other connective tissue disorders
- HIV-associated disease (benign lymphoepithelial cysts)
- Lymphoma

Fig. 19-35. Lymphoepithelial sialadenitis.

A, Lymphoepithelial sialadenitis (LESA) presenting as a markedly enlarged left parotid gland along the mandible and lateral neck region. **B**, Radiographic findings depict the presence of an enhancing, well-delineated, solid lesion with diffuse enlargement of the parotid gland.

Clinical

- More common in women than men (3:1); most common in the fourth to seventh decades of life
- Primarily affects parotid gland (80% to 85%) and submandibular gland (10% to 15%)
- Presentation includes unilateral diffuse and firm swelling of involved glands:
 - Approximately 20% may be bilateral
 - Pain may be present in up to 40% of cases.
- High proportion of cases (approximately 50% to 85%) have clinical and laboratory evidence of Sjögren syndrome (see later).
- Represents a risk factor for development of salivary gland lymphoma especially when associated with Sjögren syndrome or other connective tissue diseases (e.g., rheumatoid arthritis):
 - Estimated risk to be 44 fold
 - Majority (80%) are extranodal marginal zone (MALT) type

Pathology

Histology

- Lymphoid infiltrate with follicular hyperplasia surrounding and infiltrating salivary ducts with parenchymal atrophy, disorganization and proliferation of the ductal epithelial cells to form the lympho-epithelial lesions, the characteristic finding in LESA:
 - General solid, cystic alterations of lymphoepithelial lesions may occur:
 - Cysts may vary in size from small to large, the latter resulting in a prominent cystic lesion (cystic LESA).
 - Findings may simulate those seen in lympho-epithelial cyst and in HIV-related salivary gland disease.
- In early stage of disease glandular lumens of the lymphoepithelial lesions are preserved; with progression of disease there is near total or total effacement of the normal architecture with replacement of acinar tissue of the gland lobules with the lymphoid infiltrate as well as obliteration of the glandular lumens of the lymphoepithelial lesions, which appear as irregular-shaped nests of polygonal and spindle-shaped cells containing a variable amount of eosinophilic hyaline material.
- Overall lobular architecture of affected gland is preserved.
- Early changes include multiple scattered foci of periductal lymphoid proliferation.
- Germinal center formation within the lymphoid infiltrate varies from rare to extensive; reactive follicles often have irregular outlines and do not show expansion of the mantle or marginal zones.

Fig. 19-36. LESA.

A, Enlarged parotid gland with diffuse nodularity and tan-white to fleshy appearance. **B**, Replacement of parotid gland parenchyma by lymphocytic infiltrate with identifiable germinal centers; the proliferation is well-demarcated from adjacent salivary gland parenchyma (*extreme left side of illustration*). **C** and **D**, Characteristic appearance of lymphoepithelial lesion (island) in which there is lymphocytic infiltration of proliferating ductal epithelium with obliteration of ductal lumina surrounded by a mixed chronic inflammatory cell infiltrate. **E**, Cystic alteration of the lymphoepithelial lesion may occur ranging from an incidental finding (as depicted here) to examples in which the cysts are markedly dilated appearing as a predominantly cystic lesion (not shown).

- Interfollicular regions show small lymphocytes, scattered immunoblasts, and variable numbers of plasma cells but not in broad sheets:
 - Polyclonal (interfollicular) lymphoid infiltrate is predominantly of T-cells.
- Lymphoepithelial lesions contain lymphoid cells of B-cell lineage:
 - Evidence of clonality has been identified in these B-cell lymphocytes but in these examples there typically is:

Fig. 19-37. LESA.

A, The epithelial cells of the lymphoepithelial lesions are cytokeratin positive. **B**, CD45 reactivity is present in the lymphoid component surrounding and within the lymphoepithelial lesion. **C**, Lymphoid cell infiltrate shows immunoreactivity for the B-cell marker CD20 and **(D)** T-cell marker CD3.

- Absence of additional histologic findings supportive of a malignant lymphoma
- Absence of clinical evidence supportive of a malignant lymphoma
- An overall indolent biologic course
- Some of these examples may evolve into a malignant lymphoma (extranodal marginal zone B-cell lymphoma).
- In later stages of disease, plasma cells are more conspicuous.
- Immunohistochemistry:
 - Lymphoid component:
 - Polyclonality including reactivity for B-cell and T-cell markers:
 - B-cells > T-cells
 - Lymphoid infiltrates in LESA may contain monotypic cells that have restricted immunoglobulin pattern
 - Monotypic cell population may not be invasive and may remain localized.
 - Epithelial component:
 - Cytokeratins positive
- Molecular biology:
 - Lymphoid infiltrates may reveal heavy- and light-chain Ig gene rearrangement.
 - Presence of molecular evidence of B-cell clonality may be seen in the absence of histologic features, diagnostic for a lymphoma; the meaning and importance of this finding remains controversial:
 - Most cases with monoclonal populations have an uneventful course.
 - Significance of clonality in LESA without morphologic evidence of lymphoma remains controversial.

Differential Diagnosis

- Most important differential diagnosis of LESA is malignant lymphoma:
 - Lymphomas of the major salivary glands may or may not be associated with LESA.
 - Irrespective of the setting, most lymphomas of salivary glands are B-cell non-Hodgkin lymphomas:
 - Mucosa-associated lymphoid tissue (MALT) lymphomas most common > diffuse large B-cell lymphoma and follicular lymphoma
 - See Chapter 20 for more complete coverage of salivary gland malignant lymphomas.
 - MALT lymphomas:
 - Collars of monocytoid B-cells characterized by monomorphic, medium-sized cells with abundant, pale cytoplasm and bland, uniform nuclei, and distinct cell membranes around and infiltrating within salivary ducts forming lymphoepithelial lesions:
 - Represents the strongest clue to diagnosis of MALT lymphoma
 - Normal lobular architecture is altered with replacement of acini and ducts and invasion of the neoplastic cells into surrounding structures.
 - Immunohistochemical stains show:
 - Light chain restriction
 - Diffuse sheets of CD20+ B cells
 - B-cells show aberrant coexpression of CD43
 - t(14;18) translocation with *IgH/MALT1* fusion and trisomies 3 and 18 present in a proportion of cases and assist in differentiating malignancy from benign or borderline case
 - Monocytoid B-cell lymphomas rarely have t(14;18) translocations as frequently found in MALT lymphoma of stomach and lung (as determined by immunologic studies for the bcl-2 protein)

- Lymphoepithelial cyst
- HIV-salivary gland disease

Treatment and Prognosis

- Treatment for LESA is symptomatic relief and/or directed at specific associated disease (see [Box 19-2](#)):
 - However, owing to increased risk for developing lymphoma, parotidectomy may be performed.

Sjögren Syndrome (SS)

Definition: Chronic autoimmune disease characterized by lymphocytic infiltration of exocrine glands and epithelia in multiple organs with associated dry eyes (keratoconjunctivitis sicca) due to lacrimal gland involvement and dry mouth (xerostomia) due to salivary gland involvement.

Synonym: Autoimmune epithelitis

History

- Henrik Sjögren observed that many patients with a particular form of dry eyes (keratoconjunctivitis sicca) also had polyarthritis, dry mouth, and elevated ESR.
 - Clinical syndrome is now referred to as Sjögren syndrome (SS).
 - Virtually all patients who fit the clinical definition of SS have LESA; however, only 50% of patients with LESA have SS.

Clinical

- Overwhelming majority of patients are women representing from 80% to 90% of all cases.
- For women, median age is in the sixth decade; for men median age is in the fifth decade:
 - Rarely occurs in children
- Patients usually present with firm swelling of the affected gland with or without pain.
- Lesions may be unilateral, bilateral, or there may be successive enlargement of salivary and/or lacrimal glands.
- Affected gland may be diffusely or focally (nodular) enlarged.
- In order of occurrence, the parotid is primarily affected (83%), followed by the submandibular gland (11%), and then other sites (6%):
 - Minor salivary gland involvement is considered uncommon.
- Ocular manifestations (keratoconjunctivitis sicca) are quantitative and qualitative changes of tear film.
- Oral manifestations include dry, sticky oral mucosal surfaces, no or cloudy saliva, primary or recurrent dental carries, angular cheilitis, or patchy or generalized oral mucosal erythema with dorsal tongue fissuring and papillary atrophy.
- Diffuse swelling of the salivary glands that may be nontender or tender and is usually bilateral; the submandibular gland may be affected before the parotid gland.
- Extra-glandular manifestations include:
 - Raynaud phenomenon
 - Primary biliary cirrhosis
 - Diffuse interstitial lung disease
 - Interstitial nephritis
 - Atrophic gastritis
 - Hepatobiliary diseases
 - Neuropathies
 - Inflammatory vascular disease
- Symptoms may occur with or without autoimmune or connective tissue disease:
 - In relationship to connective tissue diseases, association with rheumatoid arthritis is much more common than other collagen vascular diseases, including systemic lupus erythematosus, scleroderma, polymyositis/dermatomyositis, mixed connective tissue disease, and polyarteritis nodosa.
 - Previously, patients were classified into two categories, including those with a connective tissue disease and those without connective tissue disease; the latter category referred to as sicca syndrome.
 - Primary or limited form of Sjögren syndrome occurs in the absence of another connective tissue disease.
 - Secondary or complete form of Sjögren syndrome includes the presence of another connective tissue disease.
 - Association with other diseases includes (but not limited to):
 - Autoimmune thyroiditis
 - Atrophic gastritis
 - Celiac disease
 - Inflammatory bowel disease
 - Primary biliary cirrhosis
 - Sinus histiocytosis with massive lymphadenopathy
- Despite the availability of many new imaging procedures, sialography has maintained its status as the imaging procedure of choice for evaluating SS:
 - Sialograms may show four different gradations of sialectasia, including punctate, globular, cavitary, and destructive.
 - Diagnostic accuracy of sialography is very high, with high sensitivity and specificity.

Laboratory Findings

- Most commonly used test in diagnosis is Schirmer test:
 - Measures wetting of standardized tear test strips applied between eyeball and lateral inferior eyelid

- Performed without anesthetic eye drops
- Score of ≤ 5 mm in 5 minutes considered positive test and objective evidence of ocular involvement:
 - This test may be reduced in normal subjects older than 60 years so should be excluded from the criteria or not considered for a diagnosis of SS in elderly subjects.
- Ocular staining score (OSS):
 - Sum of 0 to 6 score for fluorescein staining of cornea and 0 to 3 score for lissamine green staining of both the nasal and temporal bulbar conjunctivae, yielding a total score ranging from 0 to 12
 - OSS score of ≥ 3 considered positive test and objective evidence of ocular involvement
 - Assuming that individual is not currently using daily eye drops for glaucoma and has not had corneal surgery or cosmetic eyelid surgery in the last 5 years
- Laboratory evaluation includes sialochemistry with increased sodium, chloride, IgA, IgG, lactoferrin, and albumin, and decreased phosphates; mild anemia, leukopenia, eosinophilia, elevated ESR, and elevated serum immunoglobulins.
- Sjögren syndrome is characterized serologically by presence of autoantibodies against Ro/SSA and La/SSB:
 - Mechanisms by which these autoantibodies arise are not clear.
 - Most commonly detected autoantibodies are those directed against the ribonucleoproteins Ro/SSA and La/SSB, and presence of antibodies in SS is associated with early disease onset, longer disease duration, parotid gland enlargement, higher frequency of extraglandular manifestations, and more intense lymphocytic infiltration of the minor salivary glands.
 - Organ-specific autoantibodies present in SS include anti-salivary duct antibodies
 - Non-organ-specific antibodies present in SS include:
 - Rheumatoid factor (70% to 90% frequency)
 - Antinuclear antibodies (ANA)
 - Antibodies to centromere ($<5\%$)
- Antineutrophil cytoplasmic antibodies (ANCA) positivity can be found in patients with primary SS, and its detection is associated with the presence of clinical manifestations attributable to vascular involvement (cutaneous vasculitis, peripheral neuropathy, and Raynaud phenomenon).
- Patients with SS develop antibodies to three autoantigens called IFI16, KLHL12, and KLHL7:
 - These autoantigens represent family of transcription regulators.

- Antibodies to mitochondria reported in SS:
 - Found only in patients with primary biliary cirrhosis
- Plasma interleukin-6 (IL-6) elevated in primary SS:
 - Primary SS patients with celiac disease, pulmonary fibrosis or alveolitis, or peripheral nervous system symptoms had significantly higher IL-6 levels than patients without these manifestations.
 - IL-6 levels increase in parallel with the histologic grade of minor salivary gland biopsy.
 - Patients with SS have altered immunoregulation:
 - Lymphocyte-mediated destruction of exocrine glands; possibly a graft-versus host disease-like process in which the histocompatibility antigens of the ductal epithelium or lymphoid cells changes, leading to a loss of “self-recognition”

Diagnostic Criteria/Classification

- Criteria for the classification and diagnosis of SS have been suggested without universal acceptance.
- Classification criteria for SS representing a revision of the European criteria have been proposed by the American-European Consensus Group (AECG):
 - This group proposed revised international classification criteria for SS (Box 19-3) and the revised

BOX 19-3 Revised International Classification Criteria for SS

- I. Ocular symptoms
- II. Oral symptoms
- III. Ocular signs
 - a. Schirmer test (≤ 5 mm in 5 min)
 - b. Rose Bengal score or other ocular dry eye score (≥ 4 according to van Bijsterveld scoring system)
- IV. Histopathology:
 - a. Focus score of ≥ 1 (see later)
- V. Salivary gland involvement:
 - a. Unstimulated whole salivary flow (≤ 1.5 ml in 15 min)
 - b. Parotid sialography showing diffuse sialectasia (punctuate, globular, cavitory, destructive patterns)
 - c. Salivary scintigraphy showing delayed uptake, reduced concentration, and/or delayed excretion of tracer
- VI. Autoantibodies in serum to:
 - Ro (SSA) antigen
 - Lo (SSB) antigen
 - Both Ro (SSA) and Lo (SSB) antigens

Modified from Vitali C et al: European study group on classification criteria for Sjögren's syndrome. Classification criteria for Sjögren's syndrome: a revised version of the European criteria proposed by the American-European Consensus Group, *Ann Rheum Dis* 61:554-558, 2002, Table 2.

BOX 19-4 Revised Rules for Classification of SS**Primary SS**

1. The presence of any four of the six items listed in [Box 19-3](#) as long as either the histopathology (item IV) or serology (item VI) is positive
2. The presence of any three of the four objective criteria items (i.e., III, IV, V, VI)
3. The classification tree procedure represents a valid method for classification, although it should be more properly used in clinical-epidemiologic survey

Secondary SS

In patients with a potentially associated disease such as another well-defined connective tissue disease, the presence of items I or II (listed in [Box 19-3](#)) plus any two from among items III, IV, V (listed in [Box 19-3](#)) may be considered as indicative of secondary SS

Exclusionary Criteria

- Past head and neck radiation treatment
- Hepatitis C infection
- AIDS
- Pre-existing lymphoma
- Sarcoidosis
- Graft versus host disease
- Use of anticholinergic drugs

Modified from Vitali C et al: European study group on classification criteria for Sjögren's syndrome. Classification criteria for Sjögren's syndrome: a revised version of the European criteria proposed by the American-European Consensus Group, *Ann Rheum Dis* 61:554-558, 2002, Table 3.

BOX 19-5 American College of Rheumatology (ACR) Proposed Classification for SS (2012)

Applies to individuals with signs/symptoms that may be suggestive of SS, will be met in patients who have at least two of the following three objective features:

1. Positive serum anti-SSA/Ro and/or anti-SSB/La or (positive rheumatoid factor and ANA titer $\geq 1:320$)
2. Labial salivary gland biopsy exhibiting focal lymphocytic sialadenitis with a focus score ≥ 1 focus/4 mm²
3. Keratoconjunctivitis sicca with ocular staining score ≥ 3 (assuming that individual is not currently using daily eye drops for glaucoma and has not had corneal surgery or cosmetic eyelid surgery in the last 5 years)

Prior diagnosis of any of the following conditions would exclude participation in SS studies or therapeutic trials because of overlapping clinical features or interference with criteria tests:

- History of head and neck radiation treatment
- Hepatitis C infection
- Acquired immunodeficiency syndrome
- Sarcoidosis
- Amyloidosis
- Graft versus host disease
- IgG4-related disease

SS, Sjögren syndrome.

From Shiboski SC et al: American College of Rheumatology classification criteria for Sjögren's syndrome: a data-driven, expert consensus approach in the Sjögren's International Collaborative Clinical Alliance cohort, *Arthritis Care Res (Hoboken)* 64(4):475-87, 2012, Table 7.

rules for classification, including exclusionary criteria ([Box 19-4](#)).

- In 2012 American College of Rheumatology (ACR) criteria for Sjögren syndrome (SS) proposed ([Box 19-5](#)):
 - Need for new classification criteria based on apparent lack of standardization inherent to older criteria in the field and emergence of biologic agents as potential treatments
 - Also authors felt diagnosis must rely upon well-established objective tests clearly associated with systemic/autoimmune, oral, and ocular characteristics of disease, and include alternate tests only when they are diagnostically equivalent.
- Subsequent concordant studies of AECG and ACR classification criteria yielded concordant results in majority of cases, and gene expression profiling suggests that patients meeting either set of criteria are more similar to other SS participants than to healthy controls:
 - No clear evidence for increased value of new ACR criteria over old AECG criteria from clinical or biologic perspective
 - More recent studies based exclusively on objective tests, stringency of AECG criteria, and

potential therapeutic use of biologic agents in SS showed:

- Sensitivity and specificity of ACR criteria in diagnosing SS reported to be 90.37% and 88.46%, respectively
- Sensitivity of ACR criteria in diagnosing SS patients with and without labial biopsy reported to be 88.75% and 93.67 %, respectively, with specificities of 88.89% and 88.37%, respectively
- Most sensitive item adopted in ACR criteria reported to be ocular staining score with sensitivity of 85.77%
- Most specific item was the labial salivary gland biopsy with a specificity of 88.89%.
- Sensitivity and specificity of ACR criteria in diagnosing patients with SS relatively high and may serve as the diagnosis criteria in research and clinical practice.
- ACR criteria must be validated.
- Cause
 - Remains unknown
 - Likely causes are multifactorial
 - Likely possibility is autoimmune with an abnormal response to one or more unidentified antigens:

- In support of this consideration, and as detailed previously, there are several autoimmune-related diseases (e.g., autoimmune thyroiditis, inflammatory bowel disease, primary biliary cirrhosis, others), in which there is significant involvement of salivary glands.
- Another possible cause is viral, with numerous studies suggesting a link between viral infection and SS.
- Genetic predisposition has been suggested on the basis of familial aggregation, animal models, and candidate gene association studies.

Pathology

Histology

- SS is characterized by the spectrum of histomorphologic changes associated with LESA (see above).

Labial Biopsy (Fig. 19-38)

- Minor salivary glands may demonstrate histologic alterations in patients with SS indicative of changes seen in major glands; as a result of these findings as well as ease of access a diagnostic tool in patients

Fig. 19-38. Lip biopsy in Sjögren syndrome.

A, The biopsy includes overlying squamous mucosa (arrowhead) with greater than five lobules of minor salivary glands within the submucosa; within the minor salivary glands there are multiple lymphocytic foci (arrows). **B** and **C**, The lymphocytic cell clusters number greater than 50 lymphocytes so each cluster represents a focus score and in this example the focus score is more than 1 focus/4 mm²; note lymphocytic clusters are occurring in the background of normal-appearing minor salivary glands. **D**, The cellular components of each cluster are predominantly composed of mature lymphocytes as well as scattered plasma cells. These overall histologic findings support a diagnosis of Sjögren syndrome but are not 100% reliable, requiring additional confirmation. In this patient's case there was clinical evidence and elevated of Ro/SSA and La/SSB antibodies.

suspected of having SS is the labial salivary gland biopsy:

- “Focus Score” established in which foci containing 50 or more lymphocytes are counted
- Focus scores greater than 1 focus/4 mm² support diagnosis of the salivary component of SS.
- An adequate biopsy specimen for histologic assessment and lymphocytic infiltrate grading must include the following:
 - Specimen is taken from below clinically normal mucosa.
 - Sample includes at least five glands that are separated from their surrounding connective tissue.
 - Nonspecific chronic sialadenitis has been ruled out.
- Lacrimal gland biopsies may have more evident histopathologic findings for SS than labial salivary gland biopsies and recommendations include that labial salivary gland and lacrimal gland biopsies be performed in patients with suspected SS to reduce false-negative results and improve diagnostic accuracy.
- Comparison of labial biopsies versus parotid gland biopsies has shown that parotid gland biopsy adds very little to the minor salivary gland biopsy in the diagnosis of primary SS, but that parotid inflammatory changes may reflect disease duration and/or severity.

Treatment and Prognosis

- Treatment is symptomatic relief.
- Disease course is generally one of chronicity with long-term symptomatic treatment.
- Patients with sicca symptoms involving the eyes and the mouth usually do not progress, but development of (new) extraglandular manifestations occurs in most of SS patients over a 10- to 20-year follow-up period.
- In SS patients with immune-mediated extraglandular manifestation, the therapeutic approach is similar to systemic lupus erythematosus, although these therapies have relatively little effect on tear or saliva flow.
- Risk of developing a malignant lymphoma in patients with SS is markedly increased:
 - Estimated risk to be 44 fold
 - Majority (80%) are extranodal marginal zone (MALT) type.
 - More common in those patients with only sicca components of syndrome
 - Predisposing factor to development of lymphoma probably relates to prolonged immunologic and lymphoid hyperactivity
- Controversy surrounds role of viruses such as EBV, HHV-8, T-lymphotropic virus-1, and hepatitis C virus in lymphomatous transformation in setting of SS, but viruses have not definitively been found to play a role in lymphomatous transformation.
- Predictors for lymphoma development in SS remain to be definitively determined but may correlate to:
 - Recurrent or permanent swelling of major salivary glands
 - Lymphadenopathy, cryoglobulinemia, splenomegaly
 - Low complement levels of C4 and C3
 - Lymphopenia
 - Skin vasculitis or palpable purpura
 - M-component in serum or urine
 - Peripheral neuropathy, glomerulonephritis, and elevated beta₂-microglobulin
 - Additional factors may relate to
 - Genetic factors, CD4 lymphocytopenia, and ectopic germinal center-like structures in minor SG biopsies
- Malignant transformation of a benign lymphoepithelial lesion to a malignant epithelial neoplasm (malignant lymphoepithelial lesion) occurs much less frequently than transformation to lymphoma:
 - Although lymphoepithelial carcinomas of salivary glands are rare tumors, these carcinomas most likely develop as de novo neoplasms unrelated to other conditions (e.g., lymphoepithelial sialadenitis) (see Chapter 20).
 - Histologic setting is similar to benign lymphoepithelial lesion except for the presence of a malignant epithelial component instead of a benign epithelial component.
 - Increased incidence among Eskimos
 - More common in men than in women; most frequently occur in the fifth decade of life
 - Among Eskimos, the parotid gland is the most frequent site of occurrence; among Asians, the submandibular gland is most often involved.
 - Histologic picture of carcinomatous component ranges from low to high grade.
 - Some evidence linking Epstein-Barr virus (EBV) with this neoplasm but there is equal evidence showing an absence of EBV DNA in these neoplasms

Neoplasms of the Salivary Glands

CLASSIFICATION OF NEOPLASMS OF SALIVARY GLANDS

Box 20-1 contains the classification of neoplasms of the salivary glands.

GENERAL CONSIDERATIONS

- Salivary gland neoplasms account for between 2% and 6.5% of all neoplasms of the head and neck.
- Demographics vary per tumor type, but in general salivary gland neoplasm are:
 - More common in women than in men
 - Occur in all age groups, including children, but with a peak incidence in sixth to seventh decades of life
- Majority of salivary gland neoplasms occur in parotid gland
- Majority of salivary gland neoplasms are of epithelial origin, representing 80% to 90% of all neoplasms
- Benign neoplasms represent approximately 75% of all salivary gland neoplasms:
 - Most common benign neoplasm is pleomorphic adenoma

BOX 20-1 Classification of Neoplasms of the Salivary Glands

Benign Neoplasms

Epithelial

Pleomorphic adenoma
Basal cell adenoma
Canalicular adenoma
Warthin tumor
Myoepithelioma
Oncocytoma
Sclerosing polycystic adenosis
Cystadenoma
Ductal papillomas:
 Sialadenoma papilliferum
 Inverted ductal papilloma
 Intraductal papilloma
Other uncommon adenomas
 Striated duct adenoma
 Intercalated duct adenoma
 Lymphadenoma (nonsebaceous)
 Keratocystoma
 Lipoadenoma
 Apocrine adenoma
 Adenofibroma
Tumors with sebaceous differentiation
 Sebaceous adenoma
 Sebaceous lymphadenoma
Salivary gland anlage tumor
Nonepithelial
Hemangioma
Neurilemmoma/neurofibroma
Lipoma
Others

Malignant Neoplasms

Epithelial

Mucoepidermoid carcinoma
Acinic cell adenocarcinoma

Mammary analogue secretory carcinoma
Adenocarcinoma, NOS
Adenoid cystic carcinoma
Polymorphous low-grade adenocarcinoma
Carcinoma ex pleomorphic adenoma
 Invasive
 Intracapsular
 Carcinosarcoma
 Metastasizing pleomorphic adenoma
Basal cell adenocarcinoma
Epithelial-myoepithelial carcinoma
Clear cell adenocarcinoma; Hyalinizing clear cell carcinoma
Cystadenocarcinoma
Myoepithelial carcinoma
Salivary duct carcinoma
Intraductal carcinoma (low-grade cribriform
 cystadenocarcinoma; low-grade salivary duct carcinoma)
Squamous cell carcinoma
Adenosquamous carcinoma
Lymphoepithelial carcinoma
Neuroendocrine carcinomas
Undifferentiated (large-cell) carcinoma
Oncocytic carcinoma
Mucinous adenocarcinoma
Cribriform adenocarcinoma of minor salivary glands
 (CAMSG)
Sebaceous carcinoma/lymphadenocarcinoma
Sialoblastoma
Nonepithelial
Hematolymphoid
 Non-Hodgkin lymphoma
 Hodgkin lymphoma
Sarcomas

Secondary Neoplasms

- Among malignant tumors, mucoepidermoid carcinoma is most common:
 - True for adult and pediatric ages
- Mesenchymal neoplasms of salivary glands are rare:
 - Exception is in infants
 - Hemangioma and lymphangioma most common
 - Sialoblastoma and salivary gland anlage tumors occur almost exclusively in newborns and infants.
- As compared with neoplasms of major salivary glands, in which benign neoplasms represent the greater proportion of tumors, relative to minor salivary glands a greater proportion of neoplasms are malignant.
- Tumor types vary per gland involved
 - Some examples of tumors primarily (but not exclusively) occurring in major salivary glands include:
 - Warthin tumor
 - Basal cell adenoma
 - Oncocytoma
 - Acinic cell carcinoma
 - Mammary analogue secretory carcinoma
 - Basal cell adenocarcinoma
 - Epithelial-myoepithelial carcinoma
 - Carcinoma ex pleomorphic adenoma
 - Salivary duct carcinoma
 - Oncocytic carcinoma
 - Some examples of tumors primarily (but not exclusively) occurring in minor salivary glands include:
 - Canalicular adenoma (lip)
 - Ductal papillomas (lip, oral cavity)
 - Cystadenoma
 - Polymorphous low-grade adenocarcinoma (intraoral minor salivary glands)
 - Cribriform adenocarcinoma of minor salivary glands (tongue, oral cavity)
 - Cystadenocarcinoma
- Features associated with major versus minor salivary glands:
 - Major salivary gland neoplasms:
 - All are encapsulated.
 - Invasion beyond the capsule generally is diagnostic for malignancy.
 - Extension into the capsule does not represent invasion.
 - Invasion includes lesional cells into adjacent salivary gland parenchyma, perineural invasion, lymph-vascular invasion, invasion into connective tissues.
 - Rare exceptions to the above include:
 - ◻ Lymph-vascular permeation in pleomorphic adenomas
 - ◻ Metastatic pleomorphic adenoma
 - Several malignant salivary gland neoplasms may be encapsulated or noninvasive, including:
 - Mucoepidermoid carcinoma
 - Acinic cell carcinoma
 - Adenoid cystic carcinoma
 - Carcinoma ex pleomorphic adenoma (CEPA)
 - Epithelial-myoepithelial carcinoma
 - Mammary analogue secretory carcinoma
 - Except for CEPA, above list of malignant neoplasms has no known benign counterparts, so once requisite diagnostic criteria are established, a diagnosis can be rendered in the absence of invasion
 - Minor salivary gland neoplasms:
 - All are unencapsulated.
 - More common tumor types include pleomorphic adenoma, polymorphous low-grade adenocarcinoma and adenoid cystic carcinoma share growth patterns, cytomorphology, cell composition and immunohistochemical reactivity such that differentiation is predicated on presence or absence of invasion (e.g., neurotropism, LVI, soft tissue, bone)
 - Generalizations relative to salivary gland neoplasms:
 - Growth patterns:
 - ALL salivary gland neoplasms are polymorphic (i.e., more than one growth pattern).
 - Polymorphic growth does not equate to any specific diagnosis (e.g., polymorphous low-grade adenocarcinoma).
 - Cytomorphology:
 - Some benign (e.g., pleomorphic adenoma) and some histologically low-grade malignant salivary gland neoplasms (e.g., polymorphous low-grade adenocarcinoma, adenoid cystic carcinoma) may be composed of similar isomorphic cell type(s) lacking significant nuclear pleomorphism, increased mitotic activity.
 - Dual cell composition:
 - Many benign and malignant neoplasms composed of admixture of epithelial cells and myoepithelial cells as identified by:
 - ◻ Light microscopy
 - ◻ Immunohistochemical staining (cytokeratins, p63, p40, calponin, S100 protein, SMA, and/or GFAP)
 - Given above overlapping features between some benign and some malignant salivary gland neoplasms, in limited biopsies especially those including tissue fragments composed entirely or near entirely of lesional cells without surrounding tissue to evaluate for invasion, differentiation often cannot be achieved and a diagnosis of “salivary gland neoplasm, not

- further specified” is advised with the recommendation for conservative but complete excision.
- Risk factors linked to the development of salivary gland neoplasia include:
 - Radiation exposure
 - Familial or genetic predisposition
 - Tobacco use:
 - Strong association between tobacco use and the development of Warthin tumor
 - Microorganisms:
 - Epstein-Barr virus linked to lymphoepithelial carcinoma
 - Exposure to industrial chemicals
 - Similar to the thyroid gland, fine-needle aspiration biopsy (FNAB) represents the initial diagnostic modality in assessing the pathology of a salivary gland mass; FNAB is:
 - Cost effective and efficient
 - Has a sensitivity rate reported to be 81% to 98%
 - Has a specificity rate reported to be 60% to 75%
 - Has a false negative rate reported to be 5% to 10%:
 - Cytologically diagnosed as malignant but histologically proven to be benign
 - Has a false positive rate reported to be 0% to 6%:
 - Cytologically diagnosed as malignant and histologically proven to be benign
 - Those tumors in which the FNAB diagnosis is equivocal or inconclusive likely result in intraoperative consultation (i.e., frozen section analysis) to clarify and/or confirm the diagnosis (see Chapter 21 for the intraoperative diagnoses of salivary gland tumors).
 - In general, the light microscopic features of salivary gland neoplasms are distinctive so that use of immunohistochemistry is not necessarily required to arrive at a diagnosis; however, exceptions to this rule exist and immunohistochemical analysis may be required in the diagnosis and differential diagnosis of salivary gland neoplasms:
 - Immunohistochemical antigenic profile of salivary gland neoplasms often correlates to the histogenetic derivation of the tumor.
 - Tumors derived from the distal segments of the salivary duct system (intercalated ducts and acini) may take origin from a combination of epithelial and myoepithelial cells and may have different and diagnostic immunoreactivity as compared with those neoplasms that originate from more proximal segments of the duct system (striated and excretory ducts) in which myoepithelial cells are absent.
 - Some neoplasms have relatively unique markers or combination of markers, including (but not limited to):
 - DOG1 immunoreactivity in acinic cell carcinoma
 - Diffuse and strong mammaglobin and S100 protein staining in mammary analogue secretory carcinoma
 - Androgen receptor and salivary duct carcinoma
 - However, there is substantial overlap in the immunohistochemical antigenic profile among a wide variety of tumor types such that differentiating cannot be determined by immunohistochemical staining alone.
 - Immunohistochemical findings of selected salivary gland neoplasms are detailed in [Table 20-1](#).
 - SRY-related HMG-box 10 (Sox10) protein:
 - Transcription factor crucial in development of neural crest, Schwann cells, and melanocytes
 - Positive expression found in major salivary gland
 - Sox10 expression in salivary gland neoplasms reported as:
 - Positive in acinic cell carcinoma, adenoid cystic carcinoma, epithelial-myoepithelial carcinoma, myoepithelial carcinoma, pleomorphic adenoma, and carcinoma ex pleomorphic adenoma:
 - Sox10 expression specific to nuclei of acini, luminal, and abluminal cells of intercalated ducts but not in other sites
 - Negative in salivary duct carcinomas, mucoepidermoid carcinomas, oncocytic carcinoma, oncocytomas, and Warthin tumor
 - In other organ sites (e.g., breast, prostate, other) the identification of two cell types (e.g., ductal and myoepithelial or basal cells) may correlate to a benign neoplasm, whereas the presence of a single cell type may correlate to an adenocarcinoma; these criteria are not necessarily applicable to salivary gland, in that there are benign neoplasms composed of only a single cell type (e.g., monomorphic adenomas) and malignant tumors composed of dual cell types (e.g., adenoid cystic carcinoma, epithelial-myoepithelial carcinoma, others).
 - Cytogenetics and molecular genetics ([Table 20-2](#)):
 - Recent studies have identified genes correlating to specific tumor types, which can be used as adjuncts to light microscopic and immunohistochemical staining in diagnosis and differential diagnosis.
 - With increasing understanding of the biology of salivary gland neoplasms and identification of characteristic molecular signatures and genomic alterations of specific histologic subtypes, such neoplasms may be amenable to molecular targeted therapy:
 - Clinical trials exploring this approach are currently under way, and their efficacy remains to be determined.

TABLE 20-1 Immunohistochemistry* of Selective Salivary Gland Neoplasms

Tumor	PanK	LMWK	HMWK	p63	p40	S100	DOG-1	MGB	AR	GATA-3	Her-2	CD117	PLAG1
PA	+	+	+	+	+	+	–	–	–	v	–	v	+
BCA/BCAdC	+	+	+	+	+	+	–	–	–	v	–	v	v
MYO	+	+	+	+	+	+	–	–	–	v	–	v	+
MEC	+	+	+	+	+	–	–	–	–	v	–	v	–
ACC	+	+	+	–	–	–	+	–	–	–	–	–	–
MASC	+	+	+	–	–	+	–	+	–	+ (n)	–	–	–
AdCC	+	+	+	+	+	+	+ [†]	–	–	–	–	+ (lum)	–
PLGA	+	+	+	+	–	+	–	–	–	–	–	v	v
SDC	+	+	+	–	–	–	–	–	+ (n)	+ (n)	v (memb)	–	–
EMC	+	+	+	+	+	+	+ [†]	–	–	–	–	–	–
CCC/HCCC	+/+	+/+	+/+	–/+	–	–/–	–/–	–/–	–/–	–/–	–/–	–/–	–/–

*Staining characteristics vary widely among tumor types and even within the same tumor type. This table details ideal staining characteristics per tumor type, and although these staining patterns generally remain consistent, any given tumor listed may defy “convention” and show reactivity for a marker usually not associated with that tumor or may lack a marker usually associated with that tumor (e.g., p63 in myoepithelial cells).

[†]Frequently positive often showing distinctive combined apical ductal and membranous/cytoplasmic myoepithelial staining profile.

ACC, Acinic cell carcinoma; AdCC, adenoid cystic carcinoma; AR, androgen receptor; BCA, basal cell adenoma; BCAdC, basal cell adenocarcinoma; CCC, clear cell carcinoma, including hyalinizing type; DOG-1, discovered on GIST1; EMC, epithelial-myoeplithelial carcinoma; GATA-3, GATA binding protein 3; HCCC, hyalinizing clear cell carcinoma; HMWK, high molecular weight cytokeratin (e.g., CK5/6, CK14); LMWK, low molecular weight cytokeratin (e.g., CK7, CK8, CK19); lum, strong staining luminal cells; MASC, mammary analogue secretory carcinoma; MEC, mucoepidermoid carcinoma; memb, membranous; MGB, mammaglobin; MYO, myoepithelioma; n, nuclear; PA, pleomorphic adenoma; PanK, pancytokeratin (e.g., AE1/AE3; CAM5.2); PLAG1, pleomorphic adenoma gene 1; PLGA, polymorphous low-grade adenocarcinoma; SDC, salivary duct carcinoma; V, variably positive.

Specific staining characteristics:

DOG1: should be admixture of strong apical membranous, cytoplasmic and complete membranous staining

Mammaglobin: should be strong and diffuse cytoplasmic staining in MASC (same for S100 protein in this tumor)

PLAG1 immunohistochemical staining may not be confirmed by FISH analysis even for PA.

TABLE 20-2 Salivary Gland Neoplasms: Chromosomal Translocations

Tumor	Chromosomal Translocation	Gene Fusion	Percentage of Cases
Pleomorphic adenoma	Rearrangement of 8q12: t(3;8)(p21;q12) t(5;8)(p13;q12) Rearrangement of 12q13-15: t(3;12)(p14.2;q14-5) ins(9;12)(p23;q12-15)	<i>PLAG1</i> ; <i>HMG2</i>	Approximately 70%
Mucoepidermoid carcinoma	t(11;19)(q21;p13) t(11;15)(q21;q26)	<i>CRTC1-MAML2</i> <i>CRTC3-MAML2</i>	60% to 80% 6% or less
Adenoid cystic carcinoma	t(6;9)(q22-23;p23-24)	<i>MYB-NFIB</i>	80% to 90%
Mammary analogue secretory carcinoma	t(12;15)(p13;q25)	<i>ETV6-NTKR3</i>	Translocation 80% ETV6 break 99%
Hyalinizing clear cell carcinoma (HCCC) Clear cell variant of myoepithelial carcinoma (CCMC) [†]	t(12;22)(q13;q12)	<i>EWSR1-ATF1</i>	For HCCC 80% For CCMC 39% [†]
Cribriform cystadenocarcinoma of salivary glands	t(1;14)(p36.11;q12) t(X;14)(p11.4;q12)	<i>ARID1A-PRKD1</i> <i>DDX3X-PRKD1</i> Other abnormalities of <i>PRKD2</i> , <i>PRKD3</i>	To be determined but could be as high as 80%
Epithelial-myoeplithelial carcinoma	No translocation but a mutation	<i>HRAS</i> exon3, codon 61	27%*

*Chiosea SI, Miller M, Seethala RR: *HRAS* mutations in epithelial-myoeplithelial carcinoma, Head Neck Pathol 8:146-150, 2014.

[†]Includes de novo CCMC and CCMC ex pleomorphic adenoma. From Skalova A, Weinrib I, Hyrcza M, et al: Clear cell myoepithelial carcinoma of salivary glands showing EWSR1 rearrangement, Am J Surg Pathol 39:338-348, 2015.

- Prognostic factors in salivary gland tumors include:
 - Clinical staging (see below)
 - Microscopic grading:
 - Some neoplasms by definition are considered to be histologically low grade (e.g., acinic cell carcinoma, polymorphous low-grade adenocarcinoma, epithelial-myoepithelial carcinoma, basal cell adenocarcinoma, others) and other tumors are considered to be histologically high grade (e.g., salivary duct carcinoma, most cases of carcinoma ex pleomorphic adenoma, others).
 - Exceptions to the above occur such that histologically low-grade carcinomas may transform to high-grade tumors (e.g., acinic cell adenocarcinoma, others); further, there are low-grade variants of typically high-grade carcinomas, including low-grade carcinoma ex pleomorphic adenoma.
 - Some tumors such as adenocarcinoma, not otherwise specified, are histologically divided into low, intermediate, and high grade based on a variety of cytomorphologic findings.
 - Similarly, mucoepidermoid carcinoma is histologically divided into low, intermediate and high grade based on a combination of architectural and cytomorphologic findings.
 - Often but not always the histologic grade correlates to the clinical stage:
 - Low-grade tumors tend not to disseminate to regional lymph nodes and generally do not require a node dissection, whereas high-grade tumors often disseminate to regional lymph nodes, requiring a neck dissection.
- Intermediate-grade tumors may or may not disseminate to regional lymph nodes and require clinical and radiographic evaluation to determine whether there is or is not evidence of nodal metastasis; the result of this evaluation usually dictates the need for a neck dissection.
- Tumor location:
 - Some tumors occurring in a specific site have a better prognosis than the identical tumor occurring in a different location.
 - Mucoepidermoid carcinoma (MEC) of the parotid gland has an overall better prognosis than MEC of the submandibular gland.
- Facial nerve involvement:
 - Tumor involvement of the facial nerve is associated with increased morbidity (e.g., recurrence) and mortality.
- Demographics:
 - Tumors occurring in younger patients and in females are reported to have a more favorable outcome.
- Observed association salivary gland cancer and breast cancer noted for decades with recent evidence of a connection between *BRCA* gene mutations and salivary gland cancers.
- TNM classification of salivary gland carcinomas (Table 20-3)

BENIGN NEOPLASMS

PLEOMORPHIC ADENOMA (PA) (Figs. 20-1 to 20-15)

Definition: Benign neoplasm composed of cells demonstrating epithelial and myoepithelial differentiation:

- Considered a pure epithelial neoplasm with divergent differentiation that may also include mesenchymal-appearing elements (myxoid, hyaline, chondroid, and osseous areas).

Synonym: Benign mixed tumor

Clinical

- Represents most common neoplasm of salivary glands, accounting for 40% to 70% of all neoplasms of the parotid, submandibular glands, and minor salivary glands; PA of the sublingual glands is rare:
 - 80% occur in parotid gland
 - 10% occur in submandibular gland
 - 10% occur in minor salivary glands
- Slightly more common in women than men; occur over a wide age range but are most commonly seen in the third through sixth decades of life:
 - Most common salivary gland neoplasm in children and adolescents
- Most common site of occurrence is tail of the parotid gland but it may also occur in the deep lobe of the parotid, in the submandibular and sublingual glands, and in all minor salivary glands throughout the upper and lower respiratory tract:
 - PA of parotid gland occurs primarily (but not exclusively) in the superficial lobe (i.e., superficial plane to facial nerve)
 - PAs of deep lobe of parotid gland may present as a parapharyngeal space mass.
 - Involvement of minor salivary glands occurs most frequently on the palate (hard and soft), but other common sites include the upper lip and buccal mucosa.

TABLE 20-3 TNM Classification of Salivary Gland Carcinomas*

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 2 cm or less in greatest dimension without extraparenchymal extension [†]
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension without extraparenchymal extension [†]
T3	Tumor more than 4 cm in greatest dimension with extraparenchymal extension [†]
T4a	Moderately advanced disease Tumor invades skin, mandible, ear canal, and/or facial nerve
T4b	Very advanced disease Tumor invades skull base and/or pterygoid plates and/or encases carotid artery
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension, or metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension, or metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N2a	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension
N2b	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N3	Metastasis in a lymph node more than 6 cm in greatest dimension
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis present
Anatomic Stage/Prognostic Groups	
Stage I	T1N0M0
Stage II	T2N0M0
Stage III	T1N1M0
	T2N1M0
	T3N1M0
	T4aN0M0
Stage IVA	T4aN1M0
	T1N2M0
	T2N2M0
	T3N2M0
	T4aN2M0
Stage IVB	T4b AnyN M0
	Any T N3 M0
Stage IVC	Any T Any N M1

*Classification applies only to carcinoma of the major salivary glands, including parotid, submandibular and sublingual glands, and does not apply to carcinomas arising in the minor salivary glands of the upper respiratory tract.

[†]Extraparenchymal extension is clinical and macroscopic evidence of invasion of soft tissues. Microscopic evidence alone does not constitute extraparenchymal extension for classification purposes.

From Edge SB, et al: AJCC Cancer Staging Manual, ed 7, New York, 2010, Springer, p 80.

- May occur in the sinonasal tract:
 - Involve the septum (bony or cartilaginous portion) but may arise in the lateral wall
 - Tend to be myoepithelial-predominant neoplasms
- Multiple tumors or bilateral tumors are uncommon.
- Symptoms vary according to site:
 - Most are slow-growing, painless masses present for periods up to several years.
 - Other symptoms, in particular those occurring in the minor salivary glands, may include:
 - Difficulties in chewing, dysphagia, dyspnea, hoarseness, and epistaxis
 - May ulcerate overlying mucosa
- In parotid gland, the tumor typically occurs outside of the facial nerve, and facial nerve involvement typified by facial nerve paralysis is rare and, if present, should be suspicious for malignancy:
 - Infarcted PAs may uncommonly be associated with pain or facial palsy.
- Parapharyngeal space PAs:
 - Represent most common tumor of the parapharyngeal space (followed by peripheral nerve sheath tumors)
 - Usually present as an asymptomatic (cervical or intraoral) mass; other symptoms may include obstruction, unilateral conductive hearing loss, and serous otitis media

Fig. 20-1. Pleomorphic adenoma.

Pleomorphic adenomas may occur in major salivary glands, as well as minor salivary glands. **A**, Palpable parotid mass at the angle of the mandible that was firm, freely movable, and painless. **B**, Submucosal palatal swelling with intact surface epithelium. **C**, Large exophytic mass originating in the nasopharynx, hanging into the posterior oral cavity, where it was visible through the mouth. **D**, Resected large nasal septal large neoplasm (note elastic cartilage in center of image) that is circumscribed to encapsulated and on cut section appears predominantly with glistening (gelatinous) appearance.

- Parapharyngeal space is a potential space between the lateral wall of the pharynx, internal pterygoid muscle, and cervical vertebrae:
 - Other structures located within this space include cranial nerves IX through XII, great vessels of the neck, mature adipose tissue, and lymph nodes.
- Despite efforts in localization of key proteins using immunohistochemistry, the complex proteomic composition of pleomorphic adenomas (PA) has not yet been characterized.
- Matrix-assisted laser desorption/ionization imaging mass spectrometry (MALDI-imaging):
 - Allows label-free and spatially resolved detection of hundreds of proteins directly from tissue sections and of histomorphologic regions by finding co-localized molecular signals
 - Spatial segmentation of MALDI-imaging data is algorithmic method for finding regions of similar proteomic composition as functionally similar regions.
 - MALDI-imaging of pleomorphic adenoma (two cases reported to date):
 - Spatial segmentation subdivided tissue in good accordance with the tissue histology
 - Numerous molecular signals co-localized with histologically defined tissue regions were found.
 - Highlighted cellular trans-differentiation within the PA

Fig. 20-2. Axial contrast-enhanced CT scans of three different patients.

In **A**, a contrast-enhanced image, there is a large, nonhomogeneous, slightly lobulated mass in the left parotid gland. There is scattered enhancement. In **B**, there is a lobulated mass in the right parotid gland with scattered areas of calcification. In **C**, there is a large, nonhomogeneous mass in the left parotid gland. All of these patients had pleomorphic adenomas. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Figure 40-129, p 2531.)

- Spatial segmentation of MALDI-imaging data represents promising approach in emerging field of digital histologic analysis and characterization of tumors.
- Cause
 - No known etiologic factors
 - Familial occurrence rare

Pathology

Gross

- Firm, freely movable, unifocal mass:
 - Encapsulated or well-demarcated, tan-white, and solid in appearance

- May demonstrate cystic change
- Ulceration of overlying skin does not occur.
- Vary in size from a few centimeters up to large, disfiguring masses
- Minor salivary gland tumors are polypoid or lobulated, encapsulated or well-delineated, tan-white, usually measuring 1 to 2 cm but capable of attaining sizes of 7 cm or more.
- Recurrent tumors tend to be multinodular.

Fine-Needle Aspiration Biopsy

- Usually readily diagnosed by FNAB due to the presence of epithelial and stromal elements

Fig. 20-3. CT and MR of pleomorphic adenoma.

A and **B**, Axial contrast-enhanced CT scans show a mass in the left parotid gland with unsharp margins. **C**, Coronal T2-weighted MR image of the same patient shows a lobulated solitary mass in the left parotid gland. The lesion is far better seen than on the CT scans. This patient had a pleomorphic adenoma. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Figure 40-131, p 2532.)

- Morphologic diversity including:
 - Background filled with mucoid to fibromyxoid ground substance varying from fibrillar to myxomatous to chondroid and appearing:
 - Bright pink or magenta on Romanovsky stain
 - Bluish purple on Papanicolaou stain
 - Clusters of plasmacytoid or spindle-shaped (myoepithelial) cells:
 - Embedded in stromal matrix
 - Cohesive groups of epithelial cells with bland cytology including round to oval nuclei with fine-appearing chromatin:
 - Identified in continuity with the stromal material
- Other cellular elements and/or findings that can be seen include:
 - Squamous cells (with or without keratinization)
 - Oncocytic cells
 - Sebaceous cells
 - Tyrosine-like crystals appearing as crystalline deposits resembling the petals of a flower:
 - Not pathognomonic for pleomorphic adenoma as can be seen in nonneoplastic salivary gland lesions (e.g., parotid cysts) and in other neoplasms (e.g., polymorphous low-grade adenocarcinoma, others)
 - Intranuclear inclusions
- Degree of cellularity varies from case to case and even within the same case.
- Cellular pleomorphic adenomas:
 - Presence of cellular aspirate and relative absence of stromal component, especially if nuclear atypia is present, may present diagnostic problems in recognition as benign and in differentiating from carcinomas.
 - Cellular aspirates lacking stromal component and lacking nuclear atypia can be diagnosed as a “salivary gland neoplasm, not otherwise

Fig. 20-4. Parotid pleomorphic adenoma.

Resected pleomorphic adenoma from the superficial lobe of the parotid gland, showing a circumscribed to encapsulated tumor that on cut section is solid with a tan-white appearance.

specified,” which would then prompt surgical removal and histologic evaluation.

Histology

Typical (Classic) PA

- In major salivary glands are encapsulated but fibrous capsule varies in thickness and may be thin or even absent:
 - Prominently myxoid tumors often have incomplete capsules and there may be juxtaposition of the tumor to adjacent normal salivary gland.
 - May be multinodular:
 - Nodules may be separate from one another.
 - Not diagnostic for malignancy
 - May have irregular growth along periphery of lesion, including lesional cells extending into capsule and/or fat:
 - Capsular extension not diagnostic for carcinoma
 - Fat may be inherent component of tumor so that lesional cells extending into fat but still within the confines of a capsule are still within the spectrum of a benign neoplasm and not diagnostic for malignancy.
- In minor salivary glands generally not encapsulated but typically circumscribed or well demarcated:
 - Extension and involvement of surface epithelium not diagnostic feature for malignancy
- Histologic appearance includes an admixture of epithelial, myoepithelial, and stromal components.

Fig. 20-5. Fine needle aspiration.

Pleomorphic adenoma, fine-needle aspiration biopsy.

A, Background is filled with mucoid to fibromyxoid ground substance appearing bluish-purple with fibrillar appearance and associated spindle (myoepithelial) cells. **B**, Cohesive groups of epithelial cells with bland cytology including round to oval nuclei with fine nuclear chromatin and associated magenta-appearing mucoid ground substance. **C**, Clusters of plasmacytoid (myoepithelial) cells with associated chondroid-appearing matrix.

Fig. 20-6. Pleomorphic adenoma.

A, In major salivary glands, pleomorphic adenomas are encapsulated sharply demarcated from the unremarkable parotid gland parenchyma. **B**, In minor salivary glands such as seen in this palatal lesion, pleomorphic adenomas are circumscribed but not encapsulated. **C**, Characteristic components in a pleomorphic adenoma include admixture tubules/ductules and matrix stroma, the latter including hyaline (arrows) and myxoid foci. **D** and **E**, Acini or tubules are lined by ductal epithelial cells surrounded by an outer layer of modified myoepithelial cells of varying thickness. **F**, PLAG1 (nuclear) immunoreactivity.

Fig. 20-7. Cellular epithelial-predominant pleomorphic adenoma.

A, At low magnification there is a cellular neoplasm with residual identifiable chondromyxoid stroma. **B,** At higher magnification, cytologically bland-appearing epithelial cells predominate lining ductules as well as in the cellular areas.

Fig. 20-8. Cellular myoepithelial-predominant pleomorphic adenoma.

The myoepithelial cells may include **(A)** solid growth composed of plasmacytoid (hyaline) and/or **(B)** fascicular pattern of growth composed of spindle shaped cells. **C,** Myoepithelial cells are strongly p63 (nuclear) positive whether appearing spindle-shaped as seen here or plasmacytoid (hyaline) (not shown). **D,** Diffuse PLAG1 (nuclear) immunoreactivity.

**Fig. 20-8, cont'd**

E, The myoepithelial cells may be arranged in a reticular or lattice-like growth pattern within myxoid stroma or show **(F)** fascicular growth (*lower right*) adjacent to lattice-like growth pattern (*upper left*).

**Fig. 20-9. Chondromyxoid predominant pleomorphic adenoma.**

A, Low magnification showing predominance of chondromyxoid matrix with variable cellularity including identifiable tubules along the periphery (*left*) of the neoplasm. **B**, At higher magnification, identifiable tubules lined by dual cell type are present extending ("melting") into the dominant chondromyxoid stroma. **C**, In some examples only very focal isolated tubules remain (*arrowheads*) in a neoplasm with predominant chondromyxoid-appearing stroma.

Fig. 20-10. Metaplastic and retrogressive changes following aspiration.

Post-fine-needle aspiration biopsy changes may include **(A)** squamous metaplasia (*arrows*) with keratinization and intercellular bridges; **(B)** mucous cell metaplasia (*arrowheads*) and squamous metaplasia. This combination of cell types may raise concern for a possible diagnosis of mucoepidermoid carcinoma, but the presence of keratinization and intercellular bridges are not features typically associated with mucoepidermoid carcinomas. The latter are composed of epidermoid cells lacking keratinization and intercellular bridges. **C**, Infarction (*bottom*) with squamous metaplasia.

- Morphologic variability (i.e., polymorphism) can be seen from case to case and within a single neoplasm:
 - Growth patterns may include tubular/ductular, solid, cystic, trabecular, cribriform, papillary, reticular, or lattice-like and schwannoma-like.
- Duct-lining epithelial cells form the inner layer of acini or tubules and appear flattened, cuboidal, or columnar with round to oval nuclei and a variable amount of cytoplasm appearing eosinophilic to amphophilic.
- Myoepithelial component forms the outer layer and may appear:
 - Spindle-shaped, plasmacytoid (hyaline), cuboidal, epithelioid, clear-appearing cells
 - Plasmacytoid myoepithelial cells are oval with round nuclei eccentrically located and abundant eosinophilic hyaline cytoplasm
 - Absence of perinuclear Golgi zone
- Stromal component, the product of myoepithelial cells, varies in appearance from myxoid to (hyaline) chondroid to chondromyxoid and may also appear fibrous and vascular:
 - Any one or all of these components may coexist in the same neoplasm.
 - Quantity ranges from case to case and even within a given case and may be abundant or scanty.
 - Presence of any stromal component as detailed above allows for classification as

Fig. 20-11. Variant histologic findings in pleomorphic adenomas.

Other histologic findings that can be seen in association with pleomorphic adenomas may include (A) cribriform growth, which may suggest a diagnosis of adenoid cystic carcinoma, but in the setting of pleomorphic adenoma cribriform growth tends to be limited, occurring in a background of characteristic findings of pleomorphic adenoma; (B and C) schwannoma-like foci including perivascular hyalinization (B) and (C) wavy “buckled” appearing nuclei; (D) cells in schwannoma-like foci are strongly and diffusely p63 positive (nuclear), indicative of myoepithelial cells; (E) oncocytic cells focally or more extensive, the latter referred to as oncocytic type of pleomorphic adenoma; (F) sebaceous cells (arrow) within focus of squamous metaplasia;

Continued

Fig. 20-11, cont'd

(G) (extracellular) tyrosine-like crystals; and (H) psammoma bodies (*arrow*).

Fig. 20-12. Growth characteristics of pleomorphic adenoma.

Growth patterns that may raise concern but that are not diagnostic for carcinoma in pleomorphic adenomas may include (A and B) multinodular growth, including satellite nodules separate from the main mass; this finding is still acceptable within the spectrum of changes associated with pleomorphic adenomas; (C-E) capsular extension by (C) mushroom-like growth;

**Fig. 20-12, cont'd**

(D) protrusion into the capsule, or (E) scattered tubules (*arrows*) extending into the capsule. Such capsular extension may be a diagnostic feature for carcinoma in other organs (e.g., thyroid gland) but not in relationship to salivary gland neoplasms. Extension beyond the capsule into adjacent salivary gland parenchyma or fibroconnective tissue is considered invasive growth that generally equates to malignancy in salivary gland neoplasms. **F**, Extension into fat (*arrows*); the fat is within (part of) the neoplasm lying within the capsule (*arrowheads*) separating the tumor from the surrounding parotid gland parenchyma. **G**, Vascular permeation with tumor adherent to the vessel wall and not “floating” in the lumen as may be indicative of an artifactual change. Vascular permeation can infrequently be seen in a neoplasm with histologic features characteristic of pleomorphic adenoma and has generally been shown not to be associated with untoward behavior such as metastatic tumor.

pleomorphic adenoma rather than monomorphic adenoma.

- Extracellular crystalloids may be identified, particularly in the nonepithelial areas:
 - Crystalloids are more often present in PA than in any other salivary gland tumor but may be present in other tumor types, including polymorphous low-grade adenocarcinoma.
- Other cell components may include:
 - Squamous cells with or without keratinization
 - Mucous cells
 - Clear cells, sebaceous cells, oncocytic cells
 - Calcification and fat
- Minor salivary pleomorphic adenomas tend to be cellular and are circumscribed but unencapsulated.
 - Those occurring in the nasal cavity (particularly the septum) tend to have an increased plasmacytoid-appearing myoepithelial component.
- Multicentric pleomorphic adenomas are rare.
- Recurrent tumors are often multinodular and frequently chondromyxoid-predominant.

Fig. 20-13. Potential confounding findings in pleomorphic adenomas.

Cytomorphologic findings that may raise concern but that are not diagnostic for carcinoma in pleomorphic adenomas may include **(A)** presence of mitotic figures (*arrow*); numerous mitotic figures can be seen in any given pleomorphic adenoma but increased mitotic activity is not diagnostic for carcinoma. The presence of atypical mitoses (not shown) would represent a more worrisome feature for carcinoma but additional findings would still be required for a diagnosis of carcinoma. **B**, Enlarged pleomorphic and hyperchromatic bizarre-appearing (“monster”) nuclei. Generally such bizarre nuclei are focally and not diffusely identified and are thought to represent a reactive process. Diffuse nuclear atypia would represent a more worrisome feature for carcinoma but additional findings would still be required for a diagnosis of carcinoma. **C** and **D**, Broad zones of acellular hyalinization. The presence of prominent areas of acellular hyalinization is considered an atypical finding in pleomorphic adenomas that are not diagnostic for malignancy but may portend or be associated with malignant transformation (i.e., carcinoma ex pleomorphic adenoma).

- Post-fine-needle aspiration biopsy changes:
 - Secondary changes may occur following prior manipulation or fine-needle aspiration biopsy and may include:
 - Squamous metaplasia, including keratinization and/or intercellular bridges
 - Mucous cell metaplasia
 - Hemorrhage and cholesterol granuloma formation
 - Calcifications and psammomatoid concretions
 - “Pseudoinvasion” or bulging into the capsule
 - Necrosis/infarction
 - Spontaneous necrosis in a PA may occur, but the presence of necrosis/infarction in the absence of prior manipulation should raise concern for the possibility of malignancy.

Cellular Pleomorphic Adenoma

- Neoplasm showing residual foci diagnostic for pleomorphic adenoma, even if only limited in extent, but dominated by epithelial, myoepithelial, or stromal component

Fig. 20-14. Recurrent multinodular and multifocal pleomorphic adenoma.

A and **B**, Serial coronal T2-weighted MR images on a patient who had a prior left parotidectomy. There are multiple well-delineated masses in the left postoperative parotid bed. This patient had multiple recurrences of pleomorphic adenomas. **C**, Axial CT scan of a different patient who had a left parotidectomy. There are multiple low-attenuation well-delineated masses within the left parotid postoperative bed. This patient also had multiple recurrences of pleomorphic adenomas. These recurrences indicate that the original tumor capsule was violated at the time of the initial surgery. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Figure 40-146, p 2541.)

- Neoplasms with overabundance of epithelial cells, myoepithelial cells, or mesenchymal component categorized respectively as:
 - Epithelial-predominant pleomorphic adenoma
 - Myoepithelial-predominant pleomorphic adenoma
 - Chondromyxoid-predominant pleomorphic adenoma
- In association with increased cellularity there may be nuclear pleomorphism, including bizarre-appearing (“monster”) cells and scattered mitotic figures, raising additional concern for possible diagnosis of malignancy:
 - Typically, bizarre cells are limited in extent and often relegated to focal areas of the tumor.
 - Mitotic figures may be identified in any given tumor but often are limited in number.
 - Increased mitotic figures can be seen in any given neoplasm and solely in the absence of other findings does not constitute a diagnostic feature for carcinoma

Fig. 20-15. Recurrent PA.

Recurrent pleomorphic adenomas may vary in their histologic appearance but not infrequently are chondromyxoid predominant and may include numerous nodules in soft tissue of the neck. **A**, Multiple chondromyxoid-predominant pleomorphic adenoma nodules within skeletal muscle. **B**, The nodules are composed of benign cellular features lacking malignancy cellular features. Similar to capsular extension and vascular permeation, the presence of multiple nodules of otherwise cytologically benign lesional cells is acceptable within the spectrum of changes associated with (recurrent) pleomorphic adenomas and not diagnostic for metastatic carcinoma.

- Presence of atypical mitotic figures not typically found in pleomorphic adenomas
- Rare cases may show vascular permeation but by itself this feature is not indicative of malignancy:
 - Intravascular location of neoplastic cells can be confirmed by CD31, CD34, and factor VIII-related antigen immunostains.
 - Biologic significance not completely clear but evidence supports innocuous phenomenon in a majority of cases likely related to artifactual

spillage caused by tumor injury presumably by prior fine-needle aspiration or surgery.

- Despite the presence of increased cellularity even with bizarre cells and mitoses, there is absence of features raising concern for malignancy.

Atypical Pleomorphic Adenoma

- Atypical histologic features seen in PAs that may portend transformation to a carcinoma include:
 - Diffuse nuclear atypia (anaplasia)
 - Atypical mitoses
 - Prominent zones of (acellular) hyalinization
 - Pleomorphic adenomas with prominent zones of hyalinization are more likely to develop carcinoma than pleomorphic adenomas without such hyalinization.
 - Coagulative tumor necrosis
- Presence of atypical features should prompt extensive sectioning and histologic examination of the specimen to exclude findings that may be diagnostic for malignancy.

Recurrent Pleomorphic Adenoma

- Often but not always tend to be chondromyxoid predominant
- Often multinodular and may include:
 - Innumerable variably sized, well-circumscribed nodules
 - Extensive involvement of soft tissues of the neck, including into skeletal muscle and fat
 - In spite of multinodularity retain benign cytomorphologic features

For all pleomorphic adenomas:

- Histochemistry:
 - Intraluminal epithelial mucin may be demonstrated by diastase-resistant, periodic acid Schiff-positive, and mucicarmine-positive material.
 - Stromal component is alcian blue positive but mucicarmine negative
- Immunohistochemistry (IHC):
 - Epithelial cells:
 - Cytokeratins, CEA and EMA positive
 - May be CD117 (c-kit) positive
 - Myoepithelial cells:
 - Cytokeratins, p63, p40, calponin, S100 protein, glial fibrillary acidic protein, actin and vimentin positive
 - CEA and EMA negative
 - Pleomorphic adenoma gene 1 (PLAG1) consistently positive in PAs (nuclear) in epithelial and myoepithelial cells
 - SOX10 positive (nuclear) in epithelial and myoepithelial cells
 - Low proliferation indicates by Ki67 (MIB1) staining typically less than 5%:
 - Although not definitively

- Absent to rare p53 reactivity
- Weak bcl-2 reactivity

NOTE: IHC staining characteristics of PAs variable from case to case and even within a given case and do not necessarily show consistent staining patterns reported in the literature

- Molecular biology:
 - 70% of PAs are karyotypically abnormal, including:
 - 8q12 rearrangements:
 - Translocations include t(3;8)(p21;q12) and t(5;8)(p13;q12)
 - Target gene, pleomorphic adenoma gene 1 (*PLAG1*), mapped to 8q12
 - 12q14-15 rearrangements:
 - Translocations include t(9;12)(p24;q14-15) or ins(9;12)(p24;q12q15)
 - Target gene is the high mobility group protein gene, high mobility group AT-hook 2 (*HMGA2*)

NOTE: To date, *PLAG1* and *HMGA2* not reported in any other salivary gland neoplasms (except carcinoma ex pleomorphic adenoma)

- Sporadic or clonal changes not 8q12 or 12q13-15 rearrangements
- Normal karyotype may be present.

Differential Diagnosis (Table 20-4)

- In general, diagnosis of pleomorphic adenoma does not present difficulties; however, in cellular tumors with a variety of growth patterns, particularly involving minor salivary glands (i.e., intraoral), pleomorphic adenomas may prove difficult to differentiate from other tumors including:
 - Monomorphic adenoma (MA):
 - Presence or absence of mesenchymal component differentiates PA from MA.
 - Identification of mesenchymal component in any given case can be problematic, but in such a situation decision is between two benign neoplasms so treatment and prognosis are similar.
 - Polymorphous low-grade adenocarcinoma (PLGA) of minor salivary gland origin:
 - Many overlapping findings with PAs so in limited sampling will be problematic in differentiating it from PA (see immediately below for use of p63/p40 immunostaining in the differential diagnosis)
 - Adenoid cystic carcinoma:
 - In contrast to PAs, adenoid cystic carcinomas reported to have:
 - Increased proliferation indices
 - Increase in p53 staining
 - Strong bcl-2 staining
 - Further IHC findings including pairing p63 and p40 reported to assist in differentiating PA from

polymorphous low-grade adenocarcinoma (PLGA) and adenoid cystic carcinoma (AdCC) include:

- PA: p63 + (68%; 21/31) and p40+ (42%; 13/31) immunophenotype
- Discordant p63+/p40– staining pattern seen only in overtly mesenchymal chondromyxoid stroma
- Cellular PA: concordant p63+/p40+ or p63–/p40– immunophenotypes
- PLGA: consistent p63+ (100%; 11/11) and p40– (100%; 11/11) immunophenotype
- AdCC: p63 + (90%; 91 of 101) and p40+ (89%; 90/101) immunophenotype
 - Single discordant p63+/p40– case was solid variant with high-grade features
- Proliferation indices (Ki67):
 - Low proliferation indices seen in association with PA, cellular PA, and PLGA typically less than 5%
 - Proliferative indices reported to be significantly higher in AdCC (up to approximately 20%)
 - Increased proliferation indices may not be present in all cases of AdCC and by itself does not unequivocally differentiate it from PA, cellular PA, and PLGA.

CAUTIONARY NOTE: Although a p63/p40 immunohistochemical panel can be a valuable tool for making distinction between PA, PLGA, and AdCC, it is not infallible and any given example may demonstrate divergence from the reported p63/p40 immunophenotype.

- Mucoepidermoid carcinoma (MEC):
 - In those examples of PA with squamous and mucinous cell metaplasia differentiation from MEC can be somewhat problematic:
 - Presence of keratinization and intercellular bridges associated with squamous metaplasia of PA contrasts to the epidermoid component of MEC typically lacking keratinization and intercellular bridges.
 - Metaplastic PAs do not harbor translocations t(11;19) and anticipated t(11;15) resulting in *CRTC1-MAML2* and *CRTC3-MAML2* fusion transcripts, respectively, and/or *MAML2* gene rearrangement found in association with MEC.
- Deep-seated dermal adnexal neoplasm
- Mesenchymal neoplasm:
 - Peripheral nerve sheath tumor
 - Smooth muscle neoplasms

Treatment and Prognosis

- Complete surgical excision is preferred treatment:
 - Parotid gland tumors usually require lobectomy with preservation of the facial nerve.

TABLE 20-4 Intraoral Minor Salivary Gland Neoplasms: Selective Differential Diagnosis

Tumor	Encapsulation	Growth Patterns	Cytomorphology	Stroma	IHC	Cytogenetic
PA	Absent but well circumscribed	Polymorphic including tubules, ribbons, sheets, cords, cysts, trabeculae	Dual cell population: ducts/glands and myoepithelial cells; no necrosis or increased mitotic activity; intercellular hyaline material may be present	Chondromyxoid; crystalloids may be present	Positive for epithelial and myoepithelial markers: CKs, p63, p40, S100 protein, PLAG1 others; low proliferation indices	<i>PLAG1</i> <i>HMGA2</i>
CPA (E or M)	Absent but well circumscribed	Polymorphic including tubules, ribbons, sheets, cords, cysts, trabecular, fascicular, anastomosing cords	Dual cell population: ducts/glands and myoepithelial cells; for myoepithelial predominant tumors lesional cells include spindle-shaped and plasmacytoid cells but ducts/glands focally seen; no necrosis or increased mitotic activity; intercellular hyaline material may be present	Scanty but identifiable chondromyxoid stroma; crystalloids may be present	Positive for epithelial and myoepithelial markers: CKs, p63, S100 protein, others; low proliferation indices	<i>PLAG1</i> <i>HMGA2</i>
PLGA	Absent and infiltrative	Polymorphic including tubular/ductules, cribriform, solid, linear single cell, "streaming" along periphery, papillary	Isomorphic cells with minimal pleomorphism; no necrosis or increased mitotic activity; intercellular hyaline material may be present	Slate gray myxoid; crystalloids may be present	Positive for epithelial and myoepithelial markers: CKs, p63, S100 protein, others; p40 negative*; PLAG1 usually negative; low proliferation indices	None known although <i>PRKD2</i> rearrangement reported in a single case
AdCC tubular, cribriform	Absent and infiltrative	Polymorphic including cribriform, tubular/ductules, islands, cysts, nests, cords, solid	Basaloid cells with uniform, angulated, hyperchromatic nuclei, scanty cytoplasm; no necrosis or increased mitotic activity; intercellular hyaline material present	Myxoid-hyaline stroma	Positive for epithelial and myoepithelial markers: CK, p63, p40, S100 protein, others; PLAG1 negative; increase proliferation indices [†]	<i>MYB-NFIB</i>

*p40 not necessarily consistently negative in PLGA or positive in the other neoplasms.

[†]Increase proliferation indices may not be present in all cases of AdCC and by itself does not definitively differentiate it from PA, cellular PA and PLGA.

AdCC, Adenoid cystic carcinoma; CKs, cytokeratins; CPA, cellular pleomorphic adenoma; E, epithelial predominant; M, myoepithelial predominant; PA, pleomorphic adenoma; PLGA, polymorphous low-grade adenocarcinoma.

- Submandibular gland tumors usually necessitate complete removal.
- Minor salivary glands neoplasms require complete but conservative excision.
- Incomplete excision irrespective of site results in recurrent tumor:
- Increase risk of recurrence associated with:
 - Inadequate surgery:
 - Enucleation
 - Rupture or spillage during surgery
 - Chondromyxoid-predominant PAs:
 - Diffluent nature results in "spillage."
 - Variable capsular thickness coupled with tendency of tumor to invade capsule and/or bulge through capsule
 - Young age
- Recurrent tumors may be multifocal and in some cases may be widely distributed throughout the soft tissues of the neck, precluding surgical resection to control local disease:
 - Low-dose radiation may be used in this situation.
 - Presence of scar tissue in association with the recurrent tumor may present difficulties

relative to the facial nerve with adherence to the nerve.

- Preservation of the nerve with excision of the scar tissue and the entire parotid gland is recommended for recurrent tumor.
- Overall prognosis for PA is excellent with:
 - 5-year recurrence-free rate of 97%
 - 10-year recurrence-free rate of 94%
- Complications include malignant transformation (carcinoma ex pleomorphic adenoma) and the rare occurrence of so-called benign metastasizing pleomorphic adenoma.
- Surgical complications may include nerve damage and Frey syndrome (gustatory sweating).
- Features that may indicate a greater likelihood of malignant transformation include:
 - Occurrence in submandibular gland
 - Older patient age
 - Long-standing tumor
 - Larger tumor size
 - Prominent areas of acellular hyalinization
 - Increased mitotic activity including atypical mitoses
- Any salivary gland PA may show histologic features that raise concern for malignancy:
 - Neoplastic tissue within or extending through the fibrous capsule causes concern for malignant transformation; however, by itself capsular involvement in an otherwise unremarkable PA is acceptable and is not an indication of malignant transformation.
 - Rare cases of PA may show vascular permeation but by itself this feature is not indicative of malignancy.
 - Recurrent PA often have multiple foci of tumor within the normal salivary gland but these foci are usually discrete and circumscribed without cytologic atypia (they may show a prominent chondromyxoid stroma).
- Treatment for an atypical pleomorphic adenoma is similar to “conventional” pleomorphic adenoma albeit perhaps with more vigilant follow-up.

MONOMORPHIC ADENOMAS

Definition: Benign tumors of salivary glands characterized by a lack of the mesenchyme-like stromal component as seen in pleomorphic adenomas and composed exclusively of the epithelial component or less commonly, myoepithelial component, and arranged in a variety of morphologic patterns.

- Monomorphic adenomas encompass a whole group of neoplasms that are not pleomorphic adenomas.

WARTHIN TUMOR (WT)

(Figs. 20-16 through 20-22)

Definition: Benign salivary gland tumor characterized by its readily recognizable morphologic appearance composed of bilayered epithelium, including inner columnar oncocytic cells surrounded by smaller basoloid cells, and forming multiple cysts and papillary structures that are separate from a mature lymphocytic cell stroma.

Synonyms: Papillary cystadenoma lymphomatosum; adenolymphoma; cystadenolymphoma

Fig. 20-16. Imaging features of Warthin tumor.

Axial contrast-enhanced CT scan (A) and T2-weighted (B) MR image show a partially cystic mass in the left parotid gland with a thick tumor nodule along the posterior wall. This patient had a Warthin tumor. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Figure 40-157, p 2547.)

Fig. 20-17. Bilateral Warthin tumor.

Oblique frontal technetium sialograms show multiple masses with intense uptake in both parotid glands. This patient had bilateral Warthin tumors. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Figure 40-152, p 2544.)

Fig. 20-18. Warthin tumor.

The resection specimen shows a solid and multicystic lesion; the solid areas have a nodular appearance.

Clinical

- Represents second most common benign salivary gland tumor (following pleomorphic adenoma) accounting for approximately 5% to 6% of all salivary gland tumors and up to 12% of benign parotid gland tumors
- More common in men than in women:
 - Recent evidence shows marked decline in incidence in men with increased prevalence in women.
 - These demographic changes have been linked to smoking habits with a decline in use by men and an increase of use in women.
 - Smoking has been considered as an established risk factor for the development of Warthin tumor.
- Occurs over a wide age range but is most common in the fifth through seventh decades of life; uncommon to occur in the first three decades of life
- Almost exclusively involves parotid gland, particularly in the superficial lobe along the inferior pole adjacent to the angle of the mandible; rare cases reported in submandibular gland, palate, lip, tonsil, larynx, and maxillary sinus
- Bilateral tumors can be seen in up to 10% of cases and multifocal tumors in up to 12% of cases:
 - Bilateral or multifocal tumors may occur synchronously or metachronously.
- Most common symptom is painless mass; rarely is pain an associated complaint.
- May occur synchronously or metachronously with other salivary gland tumors, including:
 - Pleomorphic adenoma (most common), monomorphous adenomas, oncocytoma, basal cell adenoma, acinic cell adenocarcinoma, ductal adenocarcinoma, and adenoid cystic carcinoma
- Radiology:
 - CT scan:
 - Well-defined area of increased density in the posteroinferior segment of the superficial lobe of the parotid

Fig. 20-19. Warthin tumor, fine-needle aspiration biopsy.

A. Cytologic features are characterized by the presence of oocytic-appearing epithelial cells and mature lymphocytes (Diff-Quik). **B.** Cohesive cluster of oocytic epithelial cells with honeycomb arrangement and scattered lymphocytes (Papanicolaou).

- Radionucleotide imaging:
 - Increased uptake of technetium-99m, which does not wash out following diagnostic administration; this finding plays an important role in diagnosis and is related to the presence of oncocytes and their increased mitochondrial content.
- Cause:
 - Strong link with cigarette smoking
 - Radiation exposure has been linked as a tumorigenic factor.
 - Role of Epstein-Barr virus (EBV) in the development of Warthin tumor is controversial:
 - Some studies document the presence of EBV in the cytoplasm of luminal cells of WT, whereas other studies do not identify EBV in WT.
 - No substantiation that EBV plays a role in development of WT.

- Pathogenesis
 - Thought to develop from neoplastic transformation of entrapped salivary duct epithelium within intra- and periparotid lymph nodes during embryologic development; in support of this theory includes:
 - Ontogenically, parotid gland is last of the salivary glands to be encapsulated, resulting in either incorporation/entrapment of lymphoid tissue within the parotid or incorporation/entrapment of parotid ducts and acini within the periparotid lymph node epithelium
 - Identification in some cases of subcapsular sinuses, a normal feature of lymph nodes and not a normal feature of non-lymph node tissues (i.e., salivary glands)
 - Occurrence in periparotid lymph nodes
 - Presence of B- and T-cell markers in the lymphoid component of Warthin tumors

Pathology

Gross

- Encapsulated, soft and fluctuant, round to oval mass with a smooth or lobulated surface composed of tan-brown tissue with multiple cystic spaces from which a mucoid or brown exudate may be expressed; within the cystic spaces papillary projections are seen
- Solid areas can be identified and are noted for a white nodular appearance representative of lymphoid follicles.
- Measures from 1 to 8 cm in diameter

Fine-Needle Aspiration Biopsy

- Combination of oocytic-appearing epithelial cells and mature lymphocytes
- Oocytic epithelial cells appear in cohesive clusters as well as individual cells and may take on a honeycomb arrangement; these cells are characterized by the presence of:
 - Abundant granular and eosinophilic-appearing cytoplasm
 - Uniform round nuclei often centrally located with identifiable nucleoli
 - Distinct cell borders
 - Absence of lymphocytes in the epithelial cluster
- Occasionally, squamous (metaplastic) cells may be identified.
- Background of aspirate may appear “dirty” with cellular debris and associated lymphoid cells:
 - Given cystic character of Warthin tumor, FNAB may yield thick, tan-brown fluid.
 - The fluid may suggest the presence of mucus.
 - In conjunction with epithelial clusters and lymphoid cells this overall appearance may engender a diagnosis of mucoepidermoid carcinoma.

Fig. 20-20. Warthin tumor.

A, The tumor is encapsulated separated from the adjacent parotid parenchyma and characterized by cystic and papillary appearance and associated lymphoid proliferation. **B,** Slightly higher magnification shows the characterized features, including cyst formation and papillary architecture lined by oncocytic epithelial cells, which are demarcated from stromal lymphocytic cell infiltrate. **C,** At higher magnification the epithelial component lining the cystic spaces and papillary projections is composed of a double cell layer including inner (luminal) cells (*arrowheads*) composed of nonciliated, tall columnar cells with nuclei aligned toward the luminal aspect and prominent granular eosinophilic (oncocytic) cytoplasm and outer (basal) cells (*arrows*) composed of round to cuboidal cells with vesicular nuclei. The epithelial cells are sharply demarcated from the stromal lymphoid component.

Histology

- Papillary and cystic lesion composed of epithelial and lymphoid components
- Epithelial component lining the papillary projections composed of double layer of granular eosinophilic cells (referred to as oncocytic epithelia):
 - Inner or luminal cells:
 - Nonciliated, tall columnar cells with nuclei aligned toward the luminal aspect
 - Prominent oncocytic appearance of the cells is due to the presence of increased mitochondrial content.
 - Outer or basal cells:
 - Round, cuboidal, or polygonal cells with vesicular nuclei
- Lymphoid component predominantly composed of mature lymphocytes containing lymphoid follicles with germinal centers:
 - Epithelial component is sharply demarcated from the lymphoid component.
 - Other inflammatory cells that may be seen include plasma cells, histiocytes, mast cells, and occasional multinucleated (Langhans type) giant cells.

Fig. 20-21. Post needle aspiration changes in Warthin tumor.

Post-fine-needle aspiration biopsy findings in WT may include **(A)** tumor infarction retaining cystic and papillary architecture and **(B)** residual “ghost” outlines of columnar-appearing oncocytic epithelial cells; **C**, squamous metaplasia including mitotic figures (*arrows*); **D**, squamous and mucous cell metaplasia. The presence of squamous and mucous cell metaplasia may raise concern for a possible diagnosis of mucoepidermoid carcinoma but the changes are focal, occurring in the presence of other reactive and degenerative changes supporting a benign reactive (metaplastic) process rather than malignant transformation.

- Mucus-secreting (goblet) cells and sebaceous glands can be seen.
- Squamous metaplasia and focal necrosis may be seen in association with secondary inflammation.
- Lumens of the cysts may contain thick secretions, cholesterol crystals, cellular debris, or corpora amylacea-like laminated bodies.
- Post-fine-needle aspiration biopsy changes:
 - As is true of other tumors with prominent oncocytic cells, these tumors are subject to degenerative alterations either spontaneously or following needle aspiration (or biopsy), including:
 - Infarction and necrosis
 - Cytologic atypia
 - Metaplasia (squamous cell, mucous cell)
 - Granulation tissue
 - Acute and chronic inflammation
 - Fibrosis
 - Hemorrhage (recent and remote)
 - Pseudoinfiltrative pattern
- Metaplastic or infarcted variant of Warthin tumor:
 - Accounts for less than 10% of all Warthin tumors
 - Most likely develops following prior manipulation (e.g., fine-needle aspiration biopsy)
 - Extensive necrosis is present with ghost-like papillary structures remaining
 - Squamous and mucous cell metaplasia may be present.
 - Cytologic atypia may be prominent.
 - Increased mitotic figures but absence of atypical mitoses

Fig. 20-22. Malignant transformation of WT.

Rare example of a Warthin tumor with malignant (carcinomatous) transformation. **A**, Warthin tumor (center and right) characterized by cystic and papillary growth with more solid areas seen along the peripheral aspect of the tumor on the left. **B**, At higher magnification the solid component is a malignant undifferentiated (large-cell) carcinoma characterized by marked nuclear pleomorphism, enlarged vesicular nuclei with prominent eosinophilic nucleoli and increased mitotic activity.

- Extensive fibrosis with dense collagen and reactive myofibroblasts are present along the periphery of the tumor.
- Mixed acute and chronic inflammation, including neutrophils, mature lymphocytes, histiocytes, and foamy macrophages may be present.
- Additional alterations may include lipogranulomas, cholesterol granulomas
- Residual noninfarcted foci of Warthin tumor may be present.
- Histochemistry:
 - Phosphotungstic acid-hematoxylin (PTAH) stains demonstrate mitochondria as seen by blue-black granules in the cytoplasm of both epithelial cell layers.

- Immunohistochemistry:
 - Epithelial cells: cytokeratins positive
 - Lymphoid cells: reactivity for B-cell (CD20) and T-cell (CD3) markers, as well as CD56, CD4 (helper cells), and CD8 (suppressor cells).
 - Sox10 negative
- Cytogenetics and molecular genetics:
 - Absence of *CRTC1-MAML2* fusion:
 - Documentation in literature of this gene fusion, commonly found in mucoepidermoid carcinoma (see below), in WT but not substantiated

Differential Diagnosis

- Histology of WT so characteristic that its diagnosis presents limited difficulty
- Cystadenoma
- Oncocytic papillary cystadenoma (for those cases identified in unusual sites)
- Salivary gland tumors/lesions with oncocytic cells either focally or a predominant component including:
 - Oncocytoma; oncocytosis; mucoepidermoid carcinoma, acinic cell carcinoma, others
- Mucoepidermoid carcinoma:
 - In those examples of WT with squamous and mucinous cell metaplasia differentiation from MEC can be somewhat problematic:
 - Metaplastic WTs do not harbor translocations t(11;19) and anticipated t(11;15) resulting in *CRTC1-MAML2* and *CRTC3-MAML2* fusion transcripts, respectively, and/or *MAML2* gene rearrangement found in association with MEC.

Treatment and Prognosis

- Complete surgical excision is the preferred treatment and should include an adequate margin of uninvolved tissue as well as preservation of facial nerve.
- Locally recurrent tumor may occur and is related to inadequate excision or to multicentrically occurring neoplasms.
- Transformation to malignant Warthin tumor is exceedingly rare with an incidence of less than 0.1% and may include the:
 - Epithelial component (carcinoma ex Warthin tumor):
 - Squamous cell carcinoma (most common), oncocytic carcinoma, adenocarcinoma not otherwise specified, undifferentiated carcinoma, mucoepidermoid carcinoma, Merkel cell carcinoma:
 - Metastasis to regional lymph nodes may occur.
 - Rarely, distant metastasis may occur.
 - Lymphoid component:
 - Malignant lymphoma, usually non-Hodgkin type

Fig. 20-23. Basal cell adenoma.

The clinical presentation and appearance of a monomorphic adenoma are similar to those of a pleomorphic adenoma and include **(A)** enlarged parotid mass at angle of mandible just inferior to the ear that was painless; **(B)** resected parotid lesion appearing circumscribed to encapsulated and solid (*lower left*).

BASAL CELL ADENOMA

(Figs. 20-23 through 20-27)

Definition: Benign neoplasm characterized by proliferation of basaloid-appearing cells and absence of mesenchyme-like stromal component seen in pleomorphic adenoma.

- Subdivided into four histologic subtypes based on morphologic pattern, including:
 - Solid
 - Trabecular
 - Tubular
 - Membranous types: only one associated with unique clinicopathologic findings (see below)

Synonym: Dermal analogue tumor is another name that has been used for the membranous type of basal cell adenoma.

Clinical

- Accounts for approximately 2% of all salivary gland tumors
- No gender predilection; occurs over a wide age range from the fourth to ninth decades of life

Fig. 20-24. Cytology of basal cell adenoma.

Basal cell adenoma of the parotid gland, fine-needle aspiration. **A**, Cellular aspirate including tubular structures composed of uniform basaloid cells with hyperchromatic round to oval nuclei, high nuclear-to-cytoplasmic ratio, and scanty cytoplasm. **B**, Basement membrane-like material is present, appearing as amorphous eosinophilic deposits in association with the cellular proliferation. The basement membrane material, especially seen in association with the membranous type of basal cell adenoma, may create diagnosis difficulties in differentiation with adenoid cystic carcinoma.

- Most common site of occurrence is major salivary glands particularly in the parotid gland (superficial lobe):
 - 70% occur in parotid gland
 - Up to 20% occur in the upper lip
 - Involvement of other minor salivary glands occurs but is uncommon
- Symptoms vary according to site but most frequently presents as a freely mobile, asymptomatic mass with a growth period ranging from months to several decades
 - Lip or palatal tumors may be associated with ulceration.

Fig. 20-25. Basal cell adenoma, solid type.

A, The tumor is encapsulated and sharply demarcated from the surrounding parotid gland parenchyma and appears solid and cellular. **B,** At higher magnification the cellular component includes basaloid cells with uniform, hyperchromatic, round to oval nuclei, indistinct cytoplasm and peripheral palisading; scant stroma is present from which the epithelial islands are sharply demarcated by an intact membrane.

Fig. 20-26. Basal cell adenoma.

Growth patterns that can be seen in basal cell adenoma include **(A)** trabecular, characterized by the presence of elongated, ribbon-like pattern; **(B)** tubular, composed of multiple small duct-like structures; **(C)** membranous (so-called dermal analogue tumor), characterized by the presence of thick eosinophilic basement membrane-like material surrounding and separating the epithelial islands; **(D)** the eosinophilic basement membrane-like material is highlighted by periodic acid Schiff (PAS) staining.

Fig. 20-27. Basal cell adenoma.

A, B, Admixture of more peripherally located smaller cells with hyperchromatic nuclei and indistinct cytoplasm and more centrally located larger polygonal-shaped cells with vesicular nuclei and more abundant cytoplasm. **B,** Reduplicated basement membrane-like material within and external to the tumor nests. **C,** Squamous eddies (“keratin pearls”) with whorled appearance as well as foci of abrupt keratinization. **D,** Higher magnification of squamous eddies, which may be very focally identified (or even absent) in basal cell adenomas. Although foci of squamous differentiation can be seen in a variety of salivary gland neoplasms, it is generally absent in adenoid cystic carcinoma, making its presence a potential useful finding in excluding adenoid cystic carcinoma.

- Cause unknown
- Membranous type of basal cell adenoma:
 - Also referred to as dermal analogue tumor
 - Distinctive variant:
 - 90% occurrence in men
 - Frequently multicentric/multifocal and unencapsulated
 - Familial cases associated with:
 - Dermal cylindroma (most common)
 - Trichoepithelioma
 - Eccrine spiradenoma
 - Milia
 - Germline mutation of cylindromatosis gene (*CYLD*), tumor suppressor gene located at chromosome 16q12-q13 implicated in familial cases

- Somatic mutations of gene found in sporadic cases

Pathology

Fine-Needle Aspiration Cytology (FNAB)

- FNAB diagnosis may be problematic given overlapping features with pleomorphic adenoma, adenoid cystic carcinoma, and basal cell adenocarcinoma.
- Cellular aspirate including sheets, trabeculae, and tubular structures composed of uniform cells with hyperchromatic round to oval nuclei and scanty cytoplasm:
 - Cells are small with high nuclear-to-cytoplasmic ratio.
- Stromal component tends to be scanty.

- Extracellular basement membrane-like material may be present, especially in the membranous type of basal cell adenoma, appearing as amorphous eosinophilic material, including spheric globules, findings that may raise the diagnosis of adenoid cystic carcinoma.
- Collagenous stroma interdigitates with adjacent tumor cells:
 - This feature has been suggested as useful in differentiating basal cell adenoma from adenoid cystic carcinoma.

Gross

- Major glands:
 - Encapsulated, tan-white to red-pink, solid mass measuring up to 4 cm in diameter
- Minor salivary glands:
 - Similar to those of major salivary glands except that, although well circumscribed, they often are unencapsulated
 - May be associated with surface ulceration

Histology

- Encapsulated neoplasm that may show variety of growth patterns allowing for subclassification into:
 - Solid
 - Trabecular
 - Tubular
 - Membranous types
 - Combination of patterns can be seen in any given case.
 - Cribriform growth may be present.
- Irrespective of growth composed of two cell types:
 - Small cells with hyperchromatic nuclei and indistinct cytoplasm usually (but not always) seen at the periphery of the cell nests:
 - These cells may be arranged in a palisading pattern around the periphery of tumor cords or islands in manner similar to cutaneous basal cell carcinomas but usually without retraction artifact from the surrounding stroma.
 - Larger polygonal-shaped cells with pale-staining nuclei, more abundant but indistinct cytoplasm usually more centrally located in cell nests
 - In addition, these cells may form squamous whorls or eddies.
- Myoepithelial rich stroma may be present in some cases characterized by:
 - Stromal spindle-shaped cells
 - S100 positive but p63 and actin negative
 - Presence of stromal myoepithelial cells assists in differentiation from adenoid cystic carcinoma, which lacks such stromal cells

- Solid basal cell adenoma:
 - Most common histologic variant
 - Solid masses of basal cells composed of small, isomorphic cells with uniform, hyperchromatic, round to oval nuclei and indistinct cytoplasm
 - Peripheral aspect of these nests are characterized by nuclear palisading
 - Scant stroma is present from which the epithelial islands are sharply demarcated by an intact membrane.
 - Squamous cells and squamous whorled eddies (“keratin pearls”) can be seen as a terminal expansion of the epithelial islands.
 - Mitoses are generally absent.
- Trabecular basal cell adenoma:
 - Basal cell proliferation growing in elongated, ribbon-like (trabecular) pattern with the cell islands separated by proliferation of a prominent vascular (capillary) stroma.
- Tubular basal cell adenoma:
 - Basal cell proliferation composed of multiple small duct-like structures lined by columnar-appearing cells with uniform, hyperchromatic, round to oval nuclei
 - Tubules are well-demarcated from the stroma by an intact membrane.
 - Stroma is noteworthy for the presence of prominent vascular pattern consisting of capillaries and venules.
 - Mitoses are generally absent.
- Tubular-trabecular adenoma:
 - Presence of tubular and trabecular patterns
 - Cellular stroma composed of myoepithelial cells
- Membranous basal cell adenoma:
 - In contrast to the other types, the membranous basal cell adenoma may be multilobular and frequently unencapsulated (present in only approximately 50% of cases).
 - Characterized by the presence of thick eosinophilic hyalin membranes surrounding and separating cell islands and creating a jigsaw puzzle appearance; this material represents reduplicated basal lamina and its appearance is similar to that of the dermal cylindroma, prompting the synonym of dermal analogue tumor.
 - Eosinophilic hyalin material can also be seen within the tumor islands and is diastase-resistant periodic acid-Schiff positive.
 - Tumor nests are often separated by normal salivary gland parenchyma, giving the appearance of multifocal growth.
 - Mitoses are generally absent.
 - Perineural invasion is not seen.

- Cribriform basal cell adenoma
 - Composed of jigsaw puzzle–like lobules with multiple cystic spaces (cribriform growth) in at least 30% of a given tumor
 - Merge with more characteristic foci of basal cell adenoma
 - Absence of invasive growth
 - May be mistaken for adenoid cystic carcinoma
- Immunohistochemistry:
 - Staining patterns support ductal and myoepithelial differentiation, including:
 - Epithelial cells:
 - Cytokeratin (low molecular weight), CEA, EMA positive
 - Myoepithelial cells:
 - p63, calponin, S100 protein, actin and vimentin positive
 - Nuclear β -catenin staining may be present.
 - bcl-2 and c-kit (CD117) reactivity may be present.
- Electron microscopy:
 - Ductal cells:
 - Microvilli, tight junctions, desmosomes
 - Myoepithelial cells:
 - Abundant microfilaments, desmosomes, junctional complexes, reduplicated basal lamina
- Cytogenetics and molecular genetics:
 - Presence of *CTNNB1* (β -catenin) gene mutation
 - Loss of heterozygosity at 16q12-13:
 - Similar finding as seen in dermal cylindroma
- Association of Basal Cell Adenoma and Intercalated Duct Lesions (IDL)
 - IDL found to coexist with salivary and nonsalivary neoplasms.
 - Among salivary tumors, basal cell adenoma appears to be associated most frequently with IDL.
 - Tubular variant most commonly associated with IDL:
 - Less frequently, nontubular variants of basal cell adenoma may harbor foci of IDL.
 - Unique hybrid lesion containing basal cell adenoma and IDL with transitional area described
 - These findings have led to the hypothesis that IDL could be a precursor of basal cell adenoma.

Differential Diagnosis

- Pleomorphic adenoma:
 - From a therapeutic and prognostic perspective there is no difference in therapy or outcome between pleomorphic and monomorphic adenomas.
- Adenoid cystic carcinoma (solid type in particular)
- Basal cell adenocarcinoma
- Ameloblastoma

Treatment and Prognosis

- Complete surgical excision is preferred treatment and is curative.
- Prognosis is excellent.
- Local recurrences are unusual but may be seen and relate to inadequate surgical excision.
- Membranous basal cell adenoma is most commonly associated with recurrence:
 - Recurrence rate of 25% reported
 - May be consequence of inadequate resection due to characteristic multifocal growth
- Malignant transformation of basal cell adenomas is exceedingly rare:
 - Gives rise to other “basal” cell carcinomas:
 - Basal cell adenocarcinoma or adenoid cystic carcinoma
 - Tumors composed of a basal cell adenoma and adenoid cystic carcinoma and have been termed *hybrid tumors*
 - Gives rise to non-“basal” cell carcinomas:
 - Adenocarcinoma, not otherwise specified
 - Salivary duct carcinoma
 - Malignant transformation highest in association with the membranous type of basal cell adenoma:
 - Reported as high as 28%

CANALICULAR ADENOMA

(Figs. 20-28 through 20-30)

Definition: Benign neoplasm with predilection for upper lip and distinct histomorphologic appearance, including branching and interconnecting cords of single and double cell thick rows of columnar epithelium and a loose stromal component.

NOTE: Originally considered to be a variant of basal cell adenoma but recognized as a distinct salivary gland neoplasm.

Clinical

- No gender predilection, although reports have varied as to male predominance and female predominance; occurs over a wide age range from the fourth to ninth decades of life but most common in seventh decade
- Almost exclusively limited to oral cavity, in particular, upper lip, which accounts for 70% to 90% of these tumors:
 - Other sites of occurrence include the buccal mucosa.
 - Infrequently, arises in parotid gland and palate
- Symptoms include gradually enlarging, nonpainful, and nonulcerated nodule/mass:
 - Symptoms may be present for long periods of time (decades).
 - Multifocal nodular growths may be seen.

Fig. 20-28. Canalicular adenoma.

Canalicular adenoma of the upper lip appearing as a subepithelial swelling.

Fig. 20-29. Canalicular adenoma, fine-needle aspiration biopsy.

Cellular aspirate composed of uniform, basaloid-appearing (including a row of columnar-appearing) epithelial cells.

- Clinically, may be confused for a mucocele, sebaceous cyst, or lipoma

Pathology

Fine-Needle Aspiration

- Cellular aspirate that may include elongated, duct-like structures or tubules lined by columnar-appearing cells

Gross

- Circumscribed and/or encapsulated, tan-pink to yellow-brown, rubbery to firm nodule measuring from 0.5 to 3 cm in diameter
- Surface ulceration may be seen but is not common.
- Cystic spaces and a gelatinous mucoid material may be identified in transecting the tumor.

Histology

- Encapsulated or well-circumscribed nodules
- Not infrequently include multifocal nodules
 - Scattered nodules may be small (clinically undetectable) and may be unencapsulated.
- Consistent pattern of growth (unlike basal cell adenoma and other tumor types) and includes:
 - Double rows of columnar (basaloid) epithelial cells forming branching and interconnecting cords
 - Somewhat parallel arrangement of the rows of cells forms elongated duct-like structures resembling canals, hence the terminology of canalicular adenoma
 - Cystic dilatation of the canalicular structures may be present and may even be prominent in a given tumor.
 - Cords cut in cross-section may result in the presence of isolated tubules.
 - Alternating areas of tubules separated with closely apposed tubules is referred to as “beading,” creating an image of “beads on a string.”
- Elongated duct-like structures or tubules are lined by cuboidal to columnar cells with uniform, hyperchromatic, round to oval nuclei, variable amount of eosinophilic to amphophilic cytoplasm, and indistinct cell borders; mitoses are generally absent.
- Tubules are well demarcated from stroma by an intact membrane.
- Stroma is edematous and noteworthy for the relative absence of cellularity (scattered fibroblasts are present) and for the presence of prominent vascular pattern consisting of capillaries and venules, some with an eosinophilic cuff likely representing basal lamina and collagen.
- Histochemistry:
 - Diastase-sensitive, PAS-positive cytoplasmic granularity is seen.

Fig. 20-30. Canalicular adenoma.

Histologically, canalicular adenoma is characterized by (A) multifocal, well-circumscribed nodules; the presence of multifocal tumor should not be misconstrued as invasion; (B and C) growth pattern that includes interconnecting cords and parallel arrangement of the rows of cells to form elongated duct-like structures resembling canals; and (D) cellular component that includes double rows of columnar (basaloid) epithelial cells with uniform, hyperchromatic, round to oval nuclei, variable amount of eosinophilic cytoplasm, and indistinct cell borders. The canals and tubules are well demarcated from the stroma.

- Immunohistochemistry:
 - Cytokeratins (pancytokeratin, CK7, CK13), S100 protein and vimentin positive
 - Variable EMA reactivity
 - Distinctive GFAP linear immunoreactive pattern among cells in proximity to connective tissue interface reported
 - Little to no myoepithelial differentiation: absence of p63, calponin, smooth muscle actin, smooth muscle myosin heavy chain
 - Recent evidence based on morphologic, immunohistochemical, and ultrastructural findings support a cell of origin demonstrating features of intercalated duct cells and striated duct luminal epithelial cells, including:
 - IHC:
 - Positive nuclear staining for S100 protein, absence of CEA and GFAP
- EM:
 - Abundant junctional complexes, including desmosomes and hemidesmosomes
 - Junctional complexes are associated with large aggregates of cytoplasmic intermediate filaments.
 - Focal microvillus projections forming intercellular lumina lined by abundant junctional complexes
 - Abundant cytoplasmic rough endoplasmic reticulum (rER) adjacent to the intercellular lumina and in apical aspects of the cells; rER is also seen near the basal lamina

Differential Diagnosis

- Basal cell adenoma
- Adenoid cystic carcinoma
- Pleomorphic adenoma

- Striated duct adenoma (SDA):
 - Has immunohistochemical similarities to canalicular adenoma, including positivity for S100 and essentially absent myoid markers and p63 staining
 - Histologic findings in SDA that are distinct from canalicular adenoma (CA) include:
 - SDA has relatively eosinophilic cytoplasm as compared with CA owing to abundance of mitochondria in the striated ductal cell cytoplasm.
 - Absence in SDA of characteristic “beading” pattern and prominent stroma present in canalicular adenoma
- Ameloblastoma
- Cutaneous basal cell carcinoma
- The multifocal growth of this neoplasm that is often devoid of a capsule can be mistaken for a carcinoma with invasion into the minor salivary gland parenchyma; awareness of this tendency reduces the likelihood of the erroneous diagnosis of carcinoma.

Treatment and Prognosis

- Conservative but complete surgical excision is the preferred treatment; enucleation is not recommended.
- Recurrence following complete excision is uncommon.

ONCOCYTOMA (Fig. 20-31)

Definition: Benign tumor of salivary gland origin exclusively composed of oncocytes, which are large epithelial cells with characteristic bright eosinophilic, granular

cytoplasm due to the presence of increased intracytoplasmic mitochondrial content and the absence of myoepithelial or basal cells.

Synonym: Oxyphilic adenoma

NOTE: Oncocytic cells in salivary glands occur in the following settings:

- Oncocytic metaplasia
- Oncocytosis (nodular or diffuse)
- Oncocytoma
- Oncocytic carcinoma
- Variety of other lesions/tumors that may have oncocytic cells (e.g., Warthin tumor, oncocytic variant of mucoepidermoid carcinoma, others)

Clinical

- Rare tumor composing less than 1% of all salivary gland neoplasms
- No gender predilection; most commonly occurs in the sixth to eighth decades of life
- Most frequently involves parotid gland but may also occur in the submandibular gland as well as in minor salivary glands throughout respiratory tract
- Symptoms vary according to the site of occurrence and most frequently present as a painless mass; other symptoms include nasal or airway obstruction.
- May occur synchronously with Warthin tumor
- Radiology:
 - Similar to Warthin tumors and as a result of the mitochondrial hyperplasia, radionuclide imaging demonstrates increased uptake of technetium-99m.
- Stimulus for induction of oncocytic change is unknown but generally considered age related, rarely seen under 50 years of age and nearly always present above 70 years old:

Fig. 20-31. Parotid gland oncocytoma.

A, Thinly encapsulated tumor showing solid growth exclusively composed of cells with prominent oncocytic cytoplasm; **B,** trabecular growth pattern;

**Fig. 20-31, cont'd**

C, organoid growth pattern. **D**, At high magnification the cells are polygonal, characterized by the presence of abundant granular eosinophilic cytoplasm with round to oval, vesicular-appearing nuclei with small nucleoli; overall the cells are rather bland appearing without cytomorphic features of malignancy. **E**, Many cases show an admixture of cells with oncocytic and clear-appearing cytoplasm. **F**, Clear cell variant oncocytoma in which there is partial or complete replacement of granular eosinophilic cytoplasm by cells with clear, nongranular-appearing cytoplasm; other than cytoplasmic appearance, the findings are similar to the more conventional type of oncocytoma. **G**, p63-positive cells interspersed along periphery and/or around oncocytic lesional cells represent basal cells that are not readily identifiable by light microscopy.

- Oncocytic cell changes are not limited to salivary glands but are seen in other organs, including:
 - Thyroid gland, parathyroid glands, adrenal glands, kidney, pancreas, others
- Pathogenesis remains unclear. Some theories support a neoplastic growth, whereas others suggest a hyperplastic/metaplastic phenomenon:
 - Oncocytic tumorigenesis secondary to acquired mitochondrial dysfunction has been proposed as a plausible mechanism, but few tumors harbor mtDNA alterations within the control region to support this theory.

Pathology

Fine-Needle Aspiration Biopsy

- Smears show oncocytic cells characterized by cells with granular-appearing cytoplasm.
- Oncocytic cells are arranged in sheets, papillary fragments, and as individual cells.
- Cytologic atypia is absent or focal/limited in extent.
- Typically, there is an absence of a lymphocytic cell component, but scattered lymphoid cells may be present:
 - Presence of lymphocytes in association with oncocytic cells may raise the diagnostic consideration of a Warthin tumor.

Gross

- Major salivary glands:
 - Well-circumscribed, encapsulated, lobulated, solid mass with an orange to rust-colored appearance, rarely measuring more than 5.0 cm in diameter
- Minor salivary glands:
 - Unencapsulated with less well-delineated borders with similar appearance and measurements as those of major glands; cystic change may be seen

Histology

- Encapsulated tumor with solid, trabecular, cord-like or organoid growth pattern separated by a thin fibroconnective tissue stroma; tumors involving minor salivary glands tend to be unencapsulated with an irregular growth pattern and may demonstrate invasion of adjacent structures
- Oncocytic cells represent a cytoplasmic alteration (metaplasia) of epithelial and/or myoepithelial cells with swelling of the cytoplasm by mitochondrial hyperplasia, giving the cell a characteristic granular eosinophilic appearance by light microscopy.
- Predominant/exclusive cell is enlarged and polyhedral in shape with a distinct cell membrane and characterized by an abundant granular eosinophilic cytoplasm and a centrally placed round, vesicular-appearing nucleus.

- Absence of residual normal salivary gland parenchyma such as serous acini or ductal epithelial structures within the oncocytic proliferation:
 - Contrasts to presence of such normal components in oncocytosis
- Cellular pleomorphism, mitoses, and necrosis are infrequently seen.
- Tyrosine-like crystals, appearing needle shaped or platelike, may be present in the tumor or in adjacent tissues:
 - Psammoma bodies may be identified.
- Other cell types that may be present include:
 - Sebaceous cells
 - Squamous cells
 - Mucous (goblet) cells (rare and must exclude oncocytic variant of mucoepidermoid carcinoma)
- Oncocytes are easily traumatized and prone to degenerative alterations either spontaneously or following manipulation (e.g., after fine-needle aspiration biopsy), including:
 - Infarction and necrosis
 - Cytologic atypia
 - Metaplasia (squamous cell)
 - Granulation tissue
 - Acute and chronic inflammation
 - Fibrosis
 - Hemorrhage (recent and remote)
- Clear cell oncocytoma:
 - Histologic variant of the “classic” oncocytoma composed of clear cells:
 - Partial or complete replacement of granular eosinophilic cytoplasm by cells with clear, nongranular-appearing cytoplasm
 - Transition areas of typical oncocytes to clear cells may be present.
 - Other than cytoplasmic appearance, histology and histochemical staining are similar to the more conventional type of oncocytoma.
 - Clear cytoplasm is due in part to fixation and tissue processing artifact, and to accumulation of glycogen within the cytoplasm, which displaces the mitochondria to the periphery of the cells.
 - Metastatic renal cell carcinoma must be ruled out.
- Histochemistry:
 - Phosphotungstic acid-hematoxylin (PTAH) stains demonstrate mitochondria as seen by blue-black granules in the cytoplasm; intracytoplasmic glycogen is demonstrated by diastase-sensitive, PAS-positive granules.
- Immunohistochemistry:
 - Cytokeratin, epithelial membrane antigen positive
 - S100 protein, glial fibrillary acidic protein, actin, thyroglobulin, TTF-1, CD10, renal cell marker, and Sox10 negative

- p63 and high-molecular-weight cytokeratin (CK14) positive in cells interspersed along periphery and/or around oncocytic lesional cells:
 - Represent basal or myoepithelial cells
- Low proliferation indices by Ki67 staining
- Electron microscopy:
 - Ultrastructural characteristic that defines the oncoocyte is the presence of mitochondria within the cell cytoplasm almost to the exclusion of other cell organelles
 - Other organelles can be seen as well as basement membrane and desmosomes.

Differential Diagnosis

- Oncocytic metaplasia:
 - Transformation of ductal and acinar epithelium to oncoocytes
 - Metaplastic process is an aging phenomenon and as such oncocytic metaplasia is generally not seen in patients less than 50 years of age from which time the percentage of the population with oncocytic metaplasia increases
 - In contrast to oncocytoma, oncocytic metaplasia represents non-mass-forming focal or limited changes in one or more areas within the salivary gland.
 - May be seen in tumor cells of nearly all salivary gland tumors, including most commonly in pleomorphic adenoma and mucoepidermoid carcinoma
- Oncocytosis (also referred to as oncocytic [adenomatous] hyperplasia):
 - Proliferation of oncocytic cells within the salivary gland
 - Typically appear as nodular foci referred to as nodular oncocytic hyperplasia or nodular oncocytosis
 - May represent a diffuse alteration in the affected salivary gland referred to as diffuse oncocytosis
 - In either nodular or diffuse form may present as a clinically detectable mass lesion, presenting difficulties in differentiation from oncocytoma; the differentiation of oncocytosis from oncocytoma may not be possible due to overlapping histologic features and this differentiation may be more of an academic than practical issue because treatment and prognosis are essentially similar; however, features seen in oncocytosis that may assist in differentiating it from oncocytoma include:
 - Multiple separate nodules (two or more)
 - Unencapsulation
 - Presence within the oncocytic nodules of residual nononcocytic salivary gland parenchyma, including ductular epithelium and serous acinar cells

- Warthin tumor
- Papillary oncocytic cystadenoma
- Pleomorphic adenoma
- A number of usual salivary gland carcinomas may have oncocytic cells as either a part of the tumor or as the predominant cell type; these tumors are included in the differential diagnosis of oncocytoma, including:
 - Oncocytic carcinoma
 - Mucoepidermoid carcinoma
 - Acinic cell adenocarcinoma
 - Adenoid cystic carcinoma
- Clear cell carcinoma
- Metastatic renal cell carcinoma and thyroid carcinoma

Treatment and Prognosis

- Complete surgical excision is the preferred treatment.
- Radiotherapy is not indicated as oncoocytes are radioresistant.
- Prognosis is excellent following removal.
- Locally recurrent tumors are uncommon.
- Transformation to an oncocytic carcinoma is rare.

MYOEPITHELIOMA

(Figs. 20-32 through 20-36)

Definition: Benign salivary gland tumor predominantly or exclusively composed of cells with myoepithelial differentiation, including spindle cells, plasmacytoid cells, epithelioid cells, or clear cells, but lacking ductal differentiation or chondroid/myxochondroid stroma. Sometimes may have abundant acellular mucoid or hyalinized stroma.

Fig. 20-32. Myoepithelioma.

Parotid gland myoepithelioma appearing as a well-demarcated, smooth, and bosselated solid lesion with a tan-yellow appearance (*right*).

Fig. 20-33. Myoepithelioma of the palate.

The tumor is circumscribed separate from adjacent minor salivary glands and composed of a monomorphic cellular proliferation lacking ductal differentiation.

Synonyms: Myoepithelial adenoma; benign myoepithelial tumor

Clinical

- Accounts for approximately 2% of all salivary gland neoplasms
- No gender predilection; occurs over a wide age range but is most commonly seen in the third to sixth decades of life
- Although all salivary gland sites may be affected, the most common site of involvement is the parotid gland.
 - Second most common site is the palate (hard and soft palate)
 - Other sites may include the submandibular gland and oral minor salivary glands (e.g., retromolar region, upper lip).
- Most commonly present as a slow-growing, painless mass

Pathology

Fine-Needle Aspiration Biopsy

- Smears show bundles of uniform-appearing spindle-shaped, epithelioid/plasmacytoid, and stellate cells in sheets and dissociated forms:
 - Nuclear atypia is absent or limited in extent.
 - Occasionally, nuclear grooves/intranuclear inclusions may be identified.
 - Glandular/tubular structures not identified
 - By May-Grünwald-Giemsa staining most of the cells have a reddish cytoplasm.
 - Red to purple, myxoid matrix appearing as scanty fibrillar substance and as globules surrounded by tumor cells may be present and may suggest a diagnosis of adenoid cystic carcinoma.

Gross

- Well-demarcated, smooth, and bosselated solid lesion with a tan-white to tan-yellow appearance measuring up to 5 cm in diameter

Histology

- Encapsulated cellular neoplasm composed of spindle-shaped, plasmacytoid (hyaline) cells, epithelioid or clear cells:
 - Capsule varies in thickness but often is thin.
 - Tumors originating in minor salivary glands are circumscribed but not encapsulated.
- Growth patterns may include:
 - Fascicular
 - Solid
 - Trabecular
 - Reticular:
 - Uncommon pattern characterized by interconnecting cords with associated loose vascularized stroma (reticulated)
- Majority of myoepitheliomas are of spindle cell type:
 - Spindle-shaped cells have uniform, centrally located nuclei with dispersed nuclear chromatin and eosinophilic granular to fibrillar-appearing cytoplasm
 - Growth patterns include fascicular or swirling.
- Other cell types may include:
 - Plasmacytoid (hyaline) cells:
 - Polygonal with round to oval pyknotic-appearing nuclei, which may be eccentrically located as a result of the accumulation of eosinophilic hyaline material in the cytoplasm
 - A paranuclear clear zone (hof) and methyl green pyronine staining are not present.
 - Growth patterns include islands, sheets, cords, or isolated cells
 - Tumors composed predominantly of plasmacytoid myoepithelial cells occur in the palate.
 - A mucinous stroma may be seen in the plasmacytoid cell type.
 - Epithelioid cells:
 - Large polygonal cells with central nuclei and eosinophilic cytoplasm
 - Growth patterns include reticular, trabecular solid
 - Hyalinized stroma may be present and in conjunction with the tumor cells showing narrow interconnecting cords (so-called reticular pattern); confusion with the tubulotrabecular type of basal cell adenoma may arise.
 - Clear cells:
 - Abundant clear cytoplasm rich in glycogen (diastase-sensitive, PAS-positive)

Fig. 20-34. Myoepithelioma.

A variety of growth patterns can be seen in myoepitheliomas including (A) fascicular to storiform; (B) solid; (C) reticular characterized by interconnecting cords with associated loose vascularized stroma; (D) trabecular with stromal and perivascular hyalinization.

- Oncocytic cells:
 - Characterized by presence of abundant granular eosinophilic-appearing cytoplasm
- Mucinous cells referred to as mucinous variant of myoepithelioma:
 - Characterized by cells with abundant eosinophilic to foamy-appearing grayish-blue cytoplasm
 - Contain abundant intracellular mucin material
- For all cell types, mild to moderate cellular pleomorphism may be seen but increased mitotic activity and necrosis are uncommon.
- Stroma may be hyalinized and/or appear myxomatous.
 - Tyrosine-like crystals may be present.
- Immunohistochemistry:
 - Cytokeratins (pancytokeratin, CK14), EMA, p63, calponin, S100 protein, smooth muscle actin, smooth muscle myosin heavy chain, glial fibrillary acidic protein (GFAP), vimentin, EMA, and muscle-specific actin variably positive
 - Desmin, thyroglobulin, TTF-1, CD10, and renal cell carcinoma marker negative
- Electron microscopy:
 - Epithelial features in the form of desmosome, tight junction
 - Myoid features in the form of intracytoplasmic myofilaments with focal densities, pinocytotic vesicles
- Molecular biology:
 - Typically lacks *PLAG1* rearrangement:
 - At least one study reported *PLAG1* immunohistochemical staining in 8 myoepitheliomas
 - Lacks *EWSR1-POU5F1* or *EWSR1-PBX1* gene fusion seen in soft tissue myoepithelial tumors

Fig. 20-35. Myoepithelioma.

A variety of cell types can be seen in myoepitheliomas including (A) spindle-shaped (most common); (B) plasmacytoid; (C) epithelioid; (D) spindle-shaped and epithelioid; (E) oncocytic; and (F) clear.

Fig. 20-36. Myoepithelioma.

Immunohistochemical staining in myoepithelioma may include (A) cytokeratin (AE1/AE3); (B) p63 (nuclear); (C) S100 protein (nuclear and cytoplasmic); (D) calponin; and (E) vimentin.

- Structural alterations in chromosomes 1, 9, 12, and 13:
 - t(1;12)(q25;q12)
 - del(9)(q22.1q22.3)
 - del(13)(q12q22)

Differential Diagnosis

- Myoepithelial-predominant pleomorphic adenoma:
 - Although myoepithelial cells predominate, residual foci of pleomorphic adenoma in the form of myxochondroid stroma are present.
- Basal cell adenoma
- Myoepithelial carcinoma
- Epithelial-myoepithelial carcinoma
- Extracranial meningioma
- Peripheral nerve sheath tumors (i.e., neurilemmoma and malignant schwannoma)
- Smooth muscle tumors (i.e., leiomyoma and leiomyosarcoma)
- Extramedullary plasmacytoma
- Spindle cell squamous carcinoma
- For clear cell dominant or exclusive tumors, the differential diagnosis may include metastatic renal cell carcinoma or thyroid carcinoma.

Treatment and Prognosis

- Complete surgical excision is the preferred treatment and should include a portion of surrounding uninvolved tissue; if appropriate, a superficial parotidectomy should be performed.
- Local recurrence is related to inadequate excision.
- There is no relationship between cell type (e.g., spindle, plasmacytoid, epithelioid, clear) and prognosis.
- Malignant transformation is rare and occurs in the setting of a long-standing tumor and/or multiply recurrent tumor.

Soft Tissue Myoepithelial Tumors

- Primary myoepithelial tumors of soft tissues are uncommon.
- Classification includes:
 - Benign neoplasm (myoepithelioma)
 - Malignant neoplasms (myoepithelial carcinoma); see [Myoepithelial Carcinoma](#) later in chapter
- As compared with their salivary gland counterpart:
 - A higher proportion of myoepithelial tumors of soft tissues are malignant.
 - Unlike salivary gland myoepithelial carcinoma, in which a majority arise in association with a pleomorphic adenoma (i.e., myoepithelial carcinoma ex pleomorphic adenoma), this occurrence is rare relative to soft tissue myoepithelial carcinoma,

the majority of which occurs as a de novo malignancy.

- Identification of *EWSR1-POU5F1* or *EWSR1-PBX1* gene fusion
- Subset of cutaneous and superficial soft tissue myoepithelial tumors display distinct ductal component, closely resembling pleomorphic adenomas of salivary gland:
 - Recurrent *PLAG1* rearrangement by FISH detected in cutaneous and benign soft tissue myoepithelial tumors, majority with abundant tubuloductal differentiation
 - Leukemia inhibitory factor receptor (*LIFR*)-*PLAG1* fusion confirmed by FISH in one soft tissue myoepithelial tumor with tubular formation
 - Findings indicate that subset of cutaneous and soft tissue myoepithelial tumors appear genetically linked to salivary gland counterparts with frequent *PLAG1* gene rearrangements and occasionally *LIFR-PLAG1* fusion.

SCLEROSING POLYCYSTIC ADENOSIS (SPA)

(Figs. 20-37 and 20-38)

Definition: Rare neoplastic process of salivary glands with histologic similarities to mammary gland fibrocystic disease.

NOTE: Reported presence of associated/superimposed foci of carcinoma in situ, invasive carcinoma, local recurrence, and clonality support classification as true neoplastic lesion rather than nonneoplastic proliferation as initially considered.

Clinical

- Uncommon lesion
- More common in women than in men; occurs over wide age range from the first to the tenth decades of life with a mean of 33 years
- Most common site of occurrence is parotid gland:
 - Much less often submandibular gland and intra-oral salivary minor glands are affected.
 - Rare cases reported in other sites, including sinonasal tract
- Patients present with a slow-growing asymptomatic mass; rarely, pain and/or a “tingling” sensation have been described.
- Majority of cases present as a de novo process but a few cases have been described in association with recurrent pleomorphic adenomas or recurrent chronic parotitis
- Familial occurrence reported in two sisters, suggesting genetic predisposition

Fig. 20-37. Sclerosing polycystic adenosis.

A, Circumscribed nodular lesion demarcated from the adjacent parotid parenchyma (*left*) and characterized by variably sized cysts and the presence of sclerotic stroma. **B**, Variably sized ductules with associated sclerotic stroma. **C**, Ducts are lined by columnar to cuboidal epithelium. **D**, Cells may show the presence of brightly eosinophilic cytoplasmic granules and/or eosinophilic hyaline globules (*arrow*) that are considered highly characteristic (although not pathognomonic) for the diagnosis. Other cell types that can be seen include (**E**) apocrine-appearing cells;

Continued

Fig. 20-37, cont'd

(F) sebaceous cells; and (G) squamous metaplasia (*arrow*).

Fig. 20-38. Sclerosing polycystic adenosis.

Additional findings may include (A) intraductal hyperplasia; note presence of outer layer of flattened myoepithelial cells (*arrowheads*), which is reactive for p63 as well as other markers for myoepithelial cells (not shown); (B) micropapillary hyperplasia; (C) areas with atypical (enlarged and hyperchromatic) nuclei (*arrow*).

Pathology

Fine-Needle Aspiration Biopsy

- Aspirate characterized by flat cohesive sheets of epithelial cells with moderate amounts of finely granular oncocytic cytoplasm and enlarged round nuclei with indistinct nucleoli.
- Some epithelial groups form glandular structures with lumens.
- Background may contain small amounts of delicate mucoproteinaceous material.
- Markedly vacuolated cells as well as cells with apocrine change manifested by well-defined apical snouting may be identified.

Gross

- The lesions usually appear as a single, well-circumscribed mass but may be multinodular, ranging in size from 1 to 5 cm in greatest dimension.
- On cut section the lesions are rubbery to firm with a pale, glistening appearance.
- Small cystic foci may be apparent on gross examination.

Microscopic

- Most lesions appear as well-circumscribed and partially encapsulated nodules with a peripheral rim of normal salivary parenchyma.
- Characterized by presence of abundant sclerotic collagenous tissue containing lobular proliferations of epithelial cells with ductal/tubular and acinous differentiation:
 - Ducts vary in size from cystically dilated spaces to small ductules.
 - Epithelial lining includes simple columnar to flattened cuboidal epithelium.
- Hyperplasia of ductal and acinar epithelial cells can be identified with interconnecting bridges or anastomosing cords creating a cribriform pattern, as well as papillary growth.
- Some cells may demonstrate the presence of intensely eosinophilic cytoplasmic granules and/or hyaline globules:
 - Considered highly characteristic although not absolutely pathognomonic
- In addition, apocrine metaplasia, mucous cells, squamous cells, and sebaceous-like cells can be present.
- Degenerative changes that can be found include:
 - Partial or completely denuded epithelium of the cystic ducts with replacement by foamy (xanthomatous) macrophages
 - Cytoplasm of the epithelial cells may be replaced by abundant pale, reticulated cytoplasm, creating

a balloon-like appearance resembling sebaceous cells.

- Intraluminal epithelial proliferation may show a spectrum of alterations ranging from nondescript with mild atypia to higher degrees of epithelial dysplasia, including moderate to severe, that at times border on ductal carcinoma in situ (DCIS):
 - DCIS is histologically identical to mammary ductal carcinoma in situ, and similar to the breast lesions, the salivary gland lesions retain a myoepithelial cell layer (see below).
 - To date, single case of invasive carcinoma arising in SPA reported:
 - Invasive component composed of isolated pleomorphic cells with eosinophilic cytoplasm, large nuclei, and prominent nucleoli diffusely infiltrating normal salivary gland and with focal entrapment of normal salivary ducts
 - Carcinoma in situ identified adjacent to invasive carcinoma
- Histochemistry:
 - Granules in cells with acinar differentiation show diastase-resistant PAS-positive material.
 - These granules are mucicarmine negative, but faint mucicarmine-positive staining can be seen in scattered duct-lining cells.
- Immunohistochemistry:
 - Tubuloacinar cells are immunoreactive for cytokeratin, CEA, BRST2, progesterone receptor (80%), and estrogen receptor (20%).
 - Absence of *HER-2*
 - Myoepithelial cells reactive with variety of myoepithelial cell markers, including p63, calponin, S100 protein, and smooth muscle actin
- Cytogenetics and molecular genetics:
 - PCR analysis of patterns of X-chromosome inactivation using human androgen receptor (HUMARA) locus has shown monoclonal population of cells indicative of monoclonality.

Differential Diagnosis

- Polycystic (dysgenetic) disease (see Chapter 19):
 - Lobular collection of cystic ducts frequently with apocrine metaplasia
 - Unlike SPA, polycystic disease is usually:
 - Bilateral
 - Involves entire gland
 - Shows no acinar proliferation and has minimal fibrosis and inflammation
- Sclerosing sialadenitis:
 - Shows similarities to SPA including presence of fibrosis and inflammation
 - In contrast to SPA, fibrosis is not nodular nor are xanthomatous cells seen in association with the duct ectasia.

Treatment and Prognosis

- Complete surgical resection is preferred treatment:
 - Facial nerve sacrifice not indicated
- Recurrence of the lesion may occur following incomplete excision:
 - 30% recurrence rate reported in some studies.
- Prognosis is very good with the caveat that until longer follow-up becomes available in these patients the biologic behavior may not be completely known.
- To date, no reported metastatic disease or death due to disease reported

CYSTADENOMA (Fig. 20-39)

Definition: Rare benign epithelial tumor characterized by its predominantly cystic (unicystic, multicystic) growth and variable appearing benign epithelial-lining cells.

Synonym: Cystic duct adenoma

Clinical

- Rare tumor type
- More common in women than in men; occurs over a wide age range from the second to ninth decades but most common in the sixth decade of life; rarely occur in the first two decades of life.
- Majority occurs in minor salivary glands, including:
 - Lips > cheek > palate
 - Slightly less than half (approximately 45%) occur in the parotid gland
 - Minority of cases (less than 10%) occur in sub-mandibular gland.
- Majority present as slowly growing, painless masses; minor salivary gland lesions appear as mucosa-covered smooth nodules resembling mucocoeles.

Pathology

Gross

- On cut section these tumors show multiple, variably sized (small) cysts surrounded by salivary gland parenchyma; occasionally a single large cyst may be present.
- Tumor size in major glands varies; typically measure less than 1 cm in minor salivary gland sites

Histology

- Circumscribed lesions that may or may not be encapsulated:
 - Presence of a capsule is variably seen
 - If fibrous capsule is present, it may completely or incompletely encapsulate lesion.
- Characterized by presence of a unicystic or multicystic lesion:

- Cysts vary in size.
- Most are multicystic with cysts separated by a limited amount of intervening dense, fibrous stroma.
- Intervening stroma may be absent.
- Patchy collections of chronic inflammatory cells are often present.
- Epithelial lining cells include single layer of cuboidal to columnar epithelium with bland nuclei lacking atypical features and absent mitotic figures.
 - Tumors with two or more cell layers thick may be present but cytologic atypia is absent.
- Other cell types that may be seen include mucous, oncocytic, sebaceous, and squamous cells:
 - Usually, when these cell types are seen they are scattered and admixed with the cuboidal or columnar cells.
 - Rarely, one of these cell types, in particular mucous cells and oncocytic cells, may predominate.
- Unicystic lesions often have luminal papillary growth:
 - Papillae vary from thin to widened and ramifying projections.
 - Fibrovascular cores are present.
- Mucinous cystadenoma:
 - Includes columnar cells with basally located nuclei and intracytoplasmic mucin-positive material
 - Combination of epidermoid, intermediate, and mucous cells not identified
- Cystadenomas associated with oncocytic features and papillary growth are termed oncocytic papillary cystadenoma:
 - Often seen in association with minor salivary glands, in particular the larynx (see Section 5)
 - Usually composed of a single epithelial layer
- Other findings may include:
 - Cystic spaces containing eosinophilic fluid that may be inspissated
 - Admixed epithelial cells and inflammatory cells may be present.
 - Intraluminal psammomatoid concretions and/or crystalloids may be identified.
- Prominent solid, extraluminal growth is unusual and, if present, should be suspicious for a malignant neoplasm.

Differential Diagnosis

- Cystic lesions associated with duct obstruction:
 - Such lesions include duct ectasia, as well as salivary duct cyst.
 - Typically, duct obstruction primarily affects sub-mandibular gland

Fig. 20-39. Cystadenoma.

A, Multicystic circumscribed to encapsulated parotid gland lesion; cystic spaces containing eosinophilic fluid; the cyst epithelial lining varies from case to case and may even vary within a given case to include **(B)** single layer of cuboidal cells; **(C)** single layer of columnar cells and cuboidal appearing cells (*arrowhead*); **(D)** multilayered oncocytic cells; **(E)** multilayered epithelium with intracystic papillary growth. In all illustrated examples, there is an absence of cytologic atypia.

- Secondary changes to duct obstruction include fibrosis, acinar atrophy, squamous metaplasia, chronic inflammation, and periductal hyalinization.
- In comparison with cystadenoma, the ectatic or cystic ducts in obstructive lesions are widely separated, may be seen connected to or tracking to the obstructed duct, and usually lack the greater cytologic variability of the intraluminal epithelial proliferation seen in cystadenoma.
- Warthin tumor:
 - Characteristic bilayered epithelial layer and prominent dense lymphoid stroma with germinal centers of Warthin tumor not seen in cystadenoma, including papillary oncocytic cystadenoma
- Intraductal papilloma:
 - Almost invariable a unicystic lesion
 - Occurs in association with a dilated salivary gland duct
 - Intraluminal papillations are more complex and numerous than papillae of cystadenoma.
- Cystadenocarcinoma:
 - Presence of invasive growth differentiates cystadenoma from cystadenocarcinoma.
- Mucoepidermoid carcinoma, low-grade:
 - May share overlapping features with cystadenoma
 - Noncystic epithelial component of mucoepidermoid carcinoma includes an admixture of mucous, epidermoid, intermediate cells, which are absent in cystadenoma
 - Invasive growth, a feature often (but not always) seen in mucoepidermoid carcinoma absent in cystadenoma
- Polycystic (dysgenetic) disease:
 - Presence of diffuse involvement of the affected gland, apocrine lining epithelial cells and spheroliths seen in polycystic (dysgenetic) disease assists in differentiating it from cystadenoma.

Treatment and Prognosis

- Complete (conservative) surgical resection is curative.
- Recurrent tumor and malignant transformation rarely occur.

DUCTAL PAPILLOMAS

Definition: Group of uncommon benign epithelial salivary gland neoplasms with unique histologic features allowing for easy identification.

- Classification includes three types:
 - Sialadenoma papilliferum
 - Intraductal papilloma
 - Inverted ductal papilloma

Sialadenoma Papilliferum (Fig. 20-40)

Definition: Benign salivary gland tumor characterized by exophytic (papillary) and endophytic epithelial proliferation of mucosa or salivary duct origin.

Synonym: So named because of its similarity to the cutaneous syringocystadenoma papilliferum

Clinical

- Uncommon tumor
- More common in men than in women; occurs over a wide age range but is most frequently seen in the sixth to seventh decades of life.
- Most common site of occurrence is the palate (greater than 80%), particularly at junction of the hard and soft palates.
 - Other minor salivary glands sites of involvement include buccal mucosa, retromolar region, tonsillar pillar, lip, and nasopharynx (adenoids).
 - Major gland involvement is rare and in major glands parotid gland is most commonly affected.
- Usually presents as an asymptomatic (painless) lesion generally discovered incidentally; clinical appearance often mistaken for a papilloma; duration of symptoms may be from months to years.
- Origin is disputed; evidence supports salivary gland excretory duct rather than intercalated duct origin.

Pathology

Gross

- Well-circumscribed, papillary or verrucoid, round to oval, tan-pink-appearing lesion measuring from a few millimeters to as large as 7.0 cm
- Base of lesion is broad or pedunculated.

Histology

- Exophytic and endophytic proliferation of surface and ductal epithelium
- Surface has papillary to verrucoid growth composed of a stratified squamous epithelium with a fibrovascular connective tissue core; acanthosis and parakeratosis of the squamous epithelium can be seen.
- Merging with surface epithelium and lying immediately subjacent to squamous epithelium is an endophytic proliferation of ductal epithelium forming dilated and tortuous structures:
 - An abrupt transition from stratified squamous epithelium covering the mucosal papillary proliferation to columnar epithelium lining the ducts identified
 - Glandular component is unencapsulated.
 - Glandular component is composed of rounded or elongated and dilated ductlike structures.
 - In deeper portions ductal structures have papillary luminal projections and microcysts.

Fig. 20-40. Sialadenoma papilliferum.

A, Exophytic appearance. **B**, Endophytic appearance. **C**, The ductal epithelium is composed of an outer or luminal layer of tall columnar cells with an eosinophilic granular cytoplasm and an inner or basal cell layer of cuboidal cells with an eosinophilic granular cytoplasm; the stromal component consists of a predominantly plasma cell infiltrate admixed with mature lymphocytes forming dilated and tortuous structures.

- Absence of encapsulation and presence of poor circumscription at the base of the lesion may simulate invasive growth and be mistaken for a malignancy.
- Ductal epithelium composed of two cell layers:
 - Outer or luminal layer: tall columnar cells with an eosinophilic granular cytoplasm
 - Inner or basal cell: cuboidal cells with an eosinophilic granular cytoplasm
- Mucous cells can be seen admixed and interspersed throughout the ductal cells and in the squamous component; oncocytic cells may also be seen.
- Chronic inflammatory cell infiltrate predominantly composed of plasma cells admixed with mature lymphocytes is present within the lamina propria of the squamous mucosal component and in the stroma of the glandular component.
- Immunohistochemistry:
 - Ductal luminal cells:
 - Cytokeratins (AE1/AE3, CK7, CK19, CAM5.2), CEA, EMA, S100 protein positive
 - Basal cells:
 - CK7, CK14, S100 protein, and vimentin positive
 - Dendritic (Langerhans) cells identified within the epithelial component stain for S100 protein and CD1a positive.

Differential Diagnosis

- Papilloma of surface epithelial origin
- Inverted ductal papilloma
- Warty dyskeratoma
- Verrucous carcinoma
- Mucoepidermoid carcinoma, low grade

Treatment and Prognosis

- Complete conservative surgical excision is the preferred treatment and is curative.
- Recurrence rarely occurs.
- Rare examples of malignant transformation reported, including:
 - Epithelial-myoepithelial carcinoma
 - Mucoepidermoid carcinoma
 - Carcinoma in situ

Intraductal Papilloma (Fig. 20-41)

Definition: Benign salivary gland neoplasm characterized by unicystic duct dilatation of luminal papillary proliferation arising from a segment of interlobular or excretory duct.

Clinical

- Uncommon tumor
- No gender predilection; affects primarily adults, occurring in the fourth through seventh decades of life

Fig. 20-41. Intraductal papilloma.

Intraductal papilloma consisting of a unicystic cavity lined by one or two layers of cuboidal or columnar epithelium which give rise to numerous papillary fronds having a thin fibrovascular connective tissue core.

- Intraoral minor salivary glands most frequently involved:
 - Buccal mucosa and lips are most commonly affected.
 - Other sites of occurrence include floor of mouth, soft palate, and tongue.
 - Involvement of major glands is rare.
- Symptoms relate to a painless, well-delineated, and solitary (submucosal) mass.

Pathology

Gross

- Well-circumscribed, mucosa-covered nonulcerated nodule measuring from 0.5 to 2 cm in diameter.
- Cut section reveals a unicystic lesion containing friable tissue.

Histology

- Unicystic cavity lined by one or two layers of cuboidal or columnar epithelium with eosinophilic cytoplasm, which give rise to numerous papillary fronds filling the cavity; papillations are covered by a similar epithelium.
- Cytologic atypia is absent; no significant increase in mitotic activity
- Mucocytes in form of goblet cells are seen admixed within the ductal epithelium
- Papillations have a thin fibrovascular connective tissue core.
- Continuity of papillary projections to cyst wall is present but depending on the sections the papillae may not be seen in continuity to the cyst wall and appear to float within the lumen.
- Epithelial component is confined to cyst cavity and there are no extensions into the adjacent stromal tissue.

Differential Diagnosis

- Inverted ductal papilloma
- Papillary cystadenoma
- Low-grade papillary adenocarcinoma of the nasopharynx

Treatment and Prognosis

- Complete conservative surgical excision is the preferred treatment and is curative.

Inverted Ductal Papilloma (Fig. 20-42)

Definition: Benign salivary gland neoplasm characterized by a luminal papillary projection occurring in the terminal portions of excretory ducts arising at the junction of a salivary gland duct and oral mucosal surface epithelium with a characteristic inverted (endophytic) growth.

Synonym: Epidermoid papillary adenoma

NOTE: This minor salivary gland tumor shares histologic features with sinonasal (Schneiderian) inverted papilloma but does not share in the biologic behavior of the sinonasal (Schneiderian) inverted papilloma.

Clinical

- Rare neoplasm
- No gender predilection; occurs primarily in adults over a wide age range but is most frequently seen in the sixth decade of life
- Most common sites of occurrence include:
 - Lower lip and the buccal (vestibular) mucosa
 - Other sites of involvement include the upper lip, floor of mouth, and soft palate.
- Generally asymptomatic and presents as a slow-growing painless, nodular submucosal swelling

Fig. 20-42. Inverted ductal papilloma.

A, Well-demarcated, endophytic epithelial growth composed of thick, bulbous proliferations contiguous with but not protruding from the surface epithelium; communication with the surface by a narrow opening is seen. **B,** The neoplasm consists of basaloid-appearing epithelial cells composed of cuboidal or columnar cells with a papillary appearance along the luminal surface and squamous/epidermoid cells between which are interspersed mucous cells and microcytes.

Pathology

Gross

- Submucosal firm nodule measuring up to 1.5 cm in diameter; a small surface pore may be seen, which is contiguous with the lumen of the tumor.

Histology

- Unencapsulated but well-demarcated, endophytic epithelial growth composed of thick, bulbous proliferations that are contiguous with but not protruding from the surface epithelium; communication with the surface by a narrow opening may be seen.
- Consists of basaloid and squamous/epidermoid cells between which mucous cells and microcysts may be interspersed; cytologic atypia is absent and there is no significant increase in mitotic activity.
- Luminal surface epithelium composed of cuboidal or columnar cells with a papillary appearance
- Tumor grows downward and appears to fill a luminal cavity:
 - Endophytic growth is “pushing” into the submucosa rather than demonstrating invasion or infiltration.
- Histochemistry:
 - Mucous cells stain positively with mucicarmine and are diastase resistant, PAS positive.

Differential Diagnosis

- Inverted papilloma
- Sialadenoma papilliferum
- Mucoepidermoid carcinoma

Treatment and Prognosis

- Conservative but complete local excision is the preferred treatment and is curative.

OTHER UNCOMMON BENIGN EPITHELIAL NEOPLASMS

- Rare to uncommon benign epithelial neoplasms of salivary glands include:
 - Striated duct adenoma
 - Intercalated duct adenoma
 - Lymphadenoma (nonsebaceous)
 - Keratocystoma
 - Lipoadenoma
 - Adenofibroma
 - Apocrine adenoma
 - Salivary gland anlage tumor

Striated Duct Adenoma

Definition: Unilayered ductal tumor that recapitulates normal striated ducts.

Clinical

- Rare tumor type with very few reported cases
- Most common site of occurrence is parotid gland
 - May occur less often in minor salivary glands (palate)
- Present as a palpable mass

Pathology

- Well-circumscribed to encapsulated lesion ranging in size from 0.5 to 3.0 cm
- Composed of closely apposed small ducts with minimal intervening stroma admixed with cystic ductal spaces that may include:
 - Prominent areas with cystic changes containing colloid-like luminal contents with scalloped edges reminiscent of thyroid parenchyma
 - Focal cysts
 - Absence of cystic spaces
- Ductal epithelial cells:
 - Single layer of cuboidal to columnar eosinophilic cells with bland nuclei, eosinophilic cytoplasm, and prominent cell membranes similar to striations of normal striated ducts:
 - Eosinophilic intranuclear inclusions may be seen.
 - Focal clear cell cytoplasmic change may be present.
 - Absence of epithelial “beading” pattern with abundant stroma seen in canalicular adenoma
 - Absence of chondromyxoid stroma, basal lamina-like material
 - Absence of mitotic activity and necrosis
 - Absence of visible bilayering composed of ductal cells surrounded by basal or myoepithelial cells:
 - In contrast, normal excretory and intercalated ducts contain diffuse bilayering with basal or myoepithelial markers.
- Psammoma bodies and an associated adipocytic component may be identified.
- Immunohistochemistry:
 - Keratins (CK7, pankeratin) consistently present
 - S100 protein in >80%
 - CK5/6 (75%)
 - Generally devoid of myoepithelial cells:
 - Smooth muscle actin (SMA) negative
 - Isolated cells may be p63 positive
 - Pattern identical to striated ducts
 - Focal calponin and smooth muscle myosin heavy chain may be present, forming incomplete rim around ducts
 - Thyroglobulin and TTF1 negative
- Highly vascular lesions with numerous small capillaries, some containing large ecstatic staghorn vessels

Treatment and Prognosis

- Complete resection curative
- No recurrence or metastases

Intercalated Duct Adenoma

(Fig. 20-43)

Definition: Rare benign neoplasm of intercalated duct epithelium. See discussion in Chapter 19 on intercalated duct lesions.

Pathology

- Presence of discrete, rounded, partially to completely encapsulated nodules with well-defined contours
 - Fibrous capsule may vary in thickness and may contain entrapped, irregular-appearing ducts.
- Composed of intercalated ducts lined by single layer of cuboidal to columnar cells with small round nuclei and eosinophilic to amphophilic cytoplasm:
 - There is an absence of nuclear pleomorphism or increased mitotic activity.
 - Minimal intervening stroma present
- Occasionally acinic cells may be interspersed among the ductular structures.
- Immunohistochemistry:
 - Luminal cells reactive for cytokeratin (CK7), DOG1 (apical and membranous), S100 protein, and lysozyme
 - Basal/myoepithelial markers including p63, calponin, CK14, or smooth muscle actin highlight thin layer of myoepithelial cells around ducts:
 - Basal/myoepithelial cells are indistinct by light microscopy.

Lymphadenoma (Nonsebaceous)

(Fig. 20-44)

Definition: Rare benign tumor that is circumscribed to encapsulated and composed of epithelial nests including glands with associated prominent lymphocytic component but without islands of sebaceous cells (unlike sebaceous lymphadenoma).

Clinical

- Uncommon tumor type but more common than sebaceous lymphadenoma
- No gender predilection; primarily disease of adults
- Most commonly arises in parotid gland:
 - Less commonly arises in submandibular gland

Pathology

- Solid or cystic epithelial tumor islands:
 - Solid foci may show trabecular growth or tubules surrounded by a basement membrane-like material.

- Cystic foci may contain proteinaceous material.
- Papillary architecture may occasionally be seen.
- Cells types include squamous cells in the solid nests, cuboidal to columnar cells lining cysts, but an absence of sebaceous cells.
- Cellular components are rather bland, lacking atypical features, significant increase in mitotic activity, and an absence of necrosis.
- Epithelial components are intimately associated with a lymphoid stroma that includes a dense mature lymphocytic cell infiltrate with identifiable lymphoid follicles; this lymphoid component is believed to represent the tumor-associated lymphoid stroma, a finding that can be seen in association with other salivary gland tumors.
- Absence of atypical features, mitotic activity, and necrosis assists in differentiating lymphadenoma from a malignancy (either a primary salivary gland carcinoma or metastatic adenocarcinoma).

Treatment and Prognosis

- Surgical excision is curative.

Keratocystoma

Definition: Benign salivary gland tumor composed of multiple cystic structures and solid nests of purely squamous cells.

Clinical

- Rare tumor type
- No gender predilection; occurs over wide age range, including pediatric and adult ages
- To date, all cases limited to parotid gland
- Present as slowly growing tumors

Pathology

- Cut surface shows multilocular cystic lesions filled with keratin materials.
- Histologically:
 - Multicystic spaces and solid epithelial islands containing lamellated-appearing keratin
 - Lined by stratified squamous epithelium with keratinization, including orthokeratosis and parakeratosis but absence of granular layer
 - Stratification of epithelium always regularly oriented from the outer basal to the inner keratotic cell layer
 - Basal cell layer demarcated by basement membrane from surrounding inflamed fibrous stroma
 - Focally, outer layer shows bud-like protrusions.
 - Solid squamous cell islands surrounded by basement membrane enveloped within collagenous stroma may be present.

Fig. 20-43. Intercalated duct adenoma.

A, Intraparotid circumscribed to encapsulated cellular proliferation. **B**, Discrete, rounded nodule with well-defined contour. **C**, The tumor is composed of ducts lined by single layer of cells with small round nuclei and eosinophilic cytoplasm; there is an absence of nuclear pleomorphism or increased mitotic activity. **D**, The basal/myoepithelial component is highlighted by p63 staining. **E**, Luminal cells show apical membranous DOG-1 staining.

Fig. 20-44. Parotid gland lymphadenoma.

A, Circumscribed to thinly encapsulated tumor that at low magnification is dominated by dense lymphoid proliferation with interspersed "spaces" representing the adenomatous component. **B**, At higher magnification tubules and ductular structures composed of cuboidal to columnar cells lacking sebaceous cells are present associated with a benign lymphoid cell stroma.

- Cystic and solid structures randomly distributed without definite lobular architecture
- Lesional cells composed of uniform, bland nuclei and abundant eosinophilic cytoplasm
- Scattered mitotic figures may be seen usually limited to outer epithelial layer; atypical mitoses not present
- Foreign-body giant cell reaction to keratin debris may be present.
- Immunoreactivity for cytokeratins (AE1/AE3, CK5/6, CK14) but negative for CAM5.2, S100 protein, actin, and calponin

Treatment and Prognosis

- Complete surgical resection is curative.
- No recurrences reported

Lipoadenoma

Definition: Benign neoplasm composed predominantly of mature adipose tissue admixed with adenomatous elements.

Synonym: Sialolipoma

Clinical

- More common in men than in women; occurs over a wide age range from third to eighth decades
- Arises primarily in parotid gland:
 - Less often may occur in submandibular gland and oral minor salivary glands

Pathology

- Solitary and well-circumscribed with light brown to yellow appearance on cut section
- Histologically, composed of an admixture of cells, including:
 - Mature adipose tissue:
 - Usually dominates, representing more than 90% but reported in as little as 5% of a given tumor
 - Benign salivary gland epithelial parenchymal components:
 - Sharply demarcated from fat
 - Composed of ducts and acini:
 - Ductal dilatation may be present.
 - Extensive oncocytic cell population often present
 - Other cell types may include sebaceous cells and squamous cells.
 - Irrespective of cellular components there is an absence of cytologic atypia.
- Other common features include the presence of serous acini, ductal elements, sebaceous glands, and a patchy chronic inflammation.

Treatment and Prognosis

- Complete surgical resection is curative.
- No recurrences reported

Apocrine Adenoma

- Rare tumor type of major and minor salivary glands
- Composed of closely packed small glands lined by cells with apocrine features

Adenofibroma

- Extremely rare tumor type
- Composed of admixture of adenomatous glands and cellular spindle cell stroma:
 - Spindle cells are CD34 positive but negative for p63, S100 protein, and actin

Salivary Gland Anlage Tumor

Definition: Benign tumor with mixed epithelial and mesenchymal elements recapitulating early stages in the embryology of salivary glands between fourth and eighth weeks of development.

Synonym: Congenital pleomorphic adenoma

- See Section 3, Pharynx, for detailed discussion including illustrations.

TUMORS WITH SEBACEOUS DIFFERENTIATION

- Sebaceous tumors of salivary glands are rare and are thought to originate from sebaceous cells or sebaceous glands found in salivary glands.
- Normal sebaceous cells or glands can be found in the oral mucosa, parotid gland, and submandibular gland; sebaceous cells can also be found in intra- and periparotid lymph nodes.
- Salivary gland sebaceous cells or glands are histologically similar to their cutaneous counterparts.
- Benign sebaceous tumors of salivary glands include:
 - Sebaceous adenoma
 - Sebaceous lymphadenoma

Sebaceous Adenoma

Definition: Rare benign epithelial salivary gland tumor that is encapsulated with solid and cystic growth and composed of cells with sebaceous differentiation, as well as squamous differentiation.

Clinical

- Rare tumor accounting for 0.1% of all salivary gland tumors.
- More common in men than in women; occur over a wide age range from the third to tenth decades of life, and a mean in the sixth decade of life
- Most common site of occurrence is parotid gland
 - Other sites of occurrence include the submandibular gland and oral cavity:
 - Sites of involvement in oral cavity include the buccal mucosa and posterior mandibular region.
 - Given the presence of sebaceous cells in oral mucosa (unassociated with minor salivary gland), a definitive minor salivary gland origin cannot be confirmed.
- Generally asymptomatic and presents as a slow-growing, painless, firm mass; duration of symptoms may be from months to years.

Pathology

Gross

- Well-circumscribed, solid and cystic, tan-white– to yellow-appearing lesion ranging up to 3.0 cm in greatest dimension

Histology

- Encapsulated tumors:
 - Capsule may be complete or partial
 - In relationship to cysts capsular irregularities are present so that a well-defined capsule is not identified.
- Composed of solid nests or islands as well as cysts surrounded by fibrous stroma
- Neoplastic cells often predominated by squamous cells with associated sebaceous cells; however, sebaceous cells may predominate:
 - Sebaceous cells are characterized by:
 - Vacuolated or multivacuolated cytoplasm
 - Nuclei that are centrally located and scalloped due to lipid imprints
- Instead of solid nests, some examples have microcystic foci of closely associated ductal or cyst-like structures lined by squamous and sebaceous cells, and separated by a fibrous stroma
- Other cellular elements that can be seen include mucous cells and oncocytic cells.
- Cellular components lack atypical features with no significant increase in mitotic activity and absent necrosis.
- Fibrous stroma contains a variable amount of chronic inflammatory cells:
 - Foreign body giant cell reaction, lipogranuloma formation and collections of foamy histiocytes may be identified.
- Histochemistry:
 - Sebaceous cells contain lipid that can be stained by oil red O on frozen section.
 - Epithelial mucin stains are negative.
- Immunohistochemistry:
 - Sebaceous cells are EMA positive.

Differential Diagnosis

- Sebaceous lymphadenoma
- Sebaceous carcinoma
- Mucoepidermoid carcinoma

Treatment and Prognosis

- Conservative but complete surgical resection is curative.
- Unlike their cutaneous counterparts, salivary gland sebaceous adenomas not associated with increased risk of visceral carcinomas as may occur in Muir-Torre syndrome

Fig. 20-45. Parotid gland sebaceous lymphadenoma.

A and B, Circumscribed to encapsulated epithelial-lined multicystic tumor with lymphoid cells in the cyst wall; lymphoid follicles are present. **C,** At higher magnifications the cyst lining includes oncocytic-appearing cells, sebaceous cells and attenuated flattened epithelium. **D,** A foreign body giant cell reaction to extravasated sebum is seen within the stroma (lower left).

Sebaceous Lymphadenoma

(Fig. 20-45)

Definition: Rare benign tumor that is circumscribed to encapsulated composed epithelial nests and islands of sebaceous cells surrounded by lymphocytes, including lymphoid follicles.

Clinical

- Rare tumor
- No gender predilection; occurs primarily in the sixth to eighth decades of life
- Majority (more than 90%) occur in parotid gland or in periparotid region
- Other much less sites of occurrence include anterior midline neck and oral cavity.
- Generally asymptomatic presenting as slow-growing, painless mass; duration of symptoms may be from months to years.
- Association with Warthin tumor and basal cell adenoma, membranous type reported
- Similar to Warthin tumor, the suggestion has been made that sebaceous lymphadenoma may arise in salivary gland inclusions within a lymph node; however, there is no definitive proof that this tumor is arising in a lymph node but rather represents the so-called tumor-associated lymphoid stroma (TALP), a phenomenon that can be seen in association with

other salivary gland tumors (e.g., acinic cell carcinoma, mucoepidermoid carcinoma, others).

Pathology

Cytology

- Fine-needle aspiration biopsy:
 - Smears show clusters of epithelial cells in background of abundant lymphoid cells, macrophages, and abundant proteinaceous materials.
 - Predominant epithelial cells are large polygonal cells with abundant cytoplasm filled with multiple, uniform, small, and clear vacuoles, ill-defined cytoplasmic borders, and small centrally located round nuclei with finely granular chromatin, conspicuous nucleoli, and indented nuclear membranes.
 - Other cells include polygonal or flat cells with less or more dense cytoplasm, indistinct cell borders, and round or oval small nuclei with smooth nuclear membranes corresponding to basaloid cells.
 - Large three-dimensional clusters of nonkeratinized squamous cells with oval nuclei containing evenly distributed chromatin, and scant to moderate dense cytoplasm arranged in “stream of fish” pattern
 - Rare granulomas and cystic contents (degenerated cells, inflammatory cells, macrophages, and abundant granular debris/proteinaceous material) may also be seen.

Gross

- Well-circumscribed to encapsulated, solid to multicystic, yellow- to yellow-white-appearing lesion ranging up to 6.0 cm in greatest dimension

Histology

- May have a complete capsule but may also be partially encapsulated or unencapsulated:
 - Unencapsulated tumors have delineated or circumscribed periphery that may abut but does not infiltrate adjacent salivary gland parenchyma or connective tissues.
- Consists of islands and ductlike structures composed of squamous cells and sebaceous cells; cuboidal, columnar, and oncocytic cells may also be present
- Cysts may also be identified lined by admixture of squamous, sebaceous, and columnar cells; small intraluminal nodular excrescences may be present.
- Epithelial component intimately associated with dense lymphoid component:
 - Well-developed lymphoid follicles can be seen in many cases.
- Generally devoid of myoepithelial cells
- Foreign body giant cell reaction and collections of histiocytes may be identified in stroma, representing secondary reaction to extravasated sebum.

- Cellular epithelial components lack atypical features with no significant increase in mitotic activity and absent necrosis.
- Histochemistry:
 - Sebaceous cells contain lipid that can be stained by oil red O on frozen section.
 - Epithelial mucin stains are negative.
 - Duct epithelial cells may show mucicarminophilia.
- Immunohistochemistry:
 - Sebaceous cells are EMA positive.
 - Epithelial cells express basal cell markers including p63, 34BE12, and/or CK5/6.
 - Luminal glandular cells express CK7.
 - Lymphoid stroma is reactive for both B- and T-cell markers.
 - No evidence of HPV, EBV, and HHV-8

Differential Diagnosis

- Sebaceous adenoma
- Lymphadenoma, nonsebaceous, of salivary gland origin:
 - Similar to sebaceous lymphadenoma but lacks sebaceous cell component
 - See previously in chapter for more complete discussion.
- Warthin tumor
- Lymphoepithelial sialadenitis
- Mucoepidermoid carcinoma
- Lymphoepithelial carcinoma
- Metastatic adenocarcinoma to periparotid or intraparotid lymph node

Treatment and Prognosis

- Conservative but complete surgical resection is curative.
- Rarely, single cases of malignant transformation to sebaceous carcinoma and basal cell adenocarcinoma reported

BENIGN SOFT TISSUE TUMORS

- Benign mesenchymal tumors of salivary glands are uncommon, accounting for approximately 2% to 5% of all major salivary gland neoplasms.
- Mesenchymal neoplasms of salivary glands are rare:
 - In first 2 decades of life mesenchymal tumors represent a significant proportion of all parotid gland tumors and may in fact be more common than epithelial tumors.
 - Hemangioma and lymphangioma most common
- Benign mesenchymal tumors of salivary glands much more common than salivary gland sarcomas
- Benign mesenchymal tumors account for less than 5% of all salivary gland tumors

- Parotid gland is most common site of occurrence:
 - >95% arise in parotid gland
- Although virtually any mesenchymal tumor can occur, among all salivary gland mesenchymal tumors the most common are of vascular origin, including hemangiomas.
 - Much less common benign mesenchymal tumors that may be seen in salivary glands include:
 - Lymphangioma
 - Lipoma
 - Benign peripheral nerve sheath tumors (i.e., schwannoma, neurofibroma)
 - Solitary fibrous tumor
 - Nodular fasciitis
 - Giant cell tumor
- Consumptive coagulopathy disorder (i.e., Kasabach-Merritt syndrome)
- Intraparotid hemangiomas in adults are uncommon.

Pathology

Gross

- Lobulated, dark red tumor measuring from 2 to 8 cm in diameter
- Overlying skin may have a bluish discoloration accentuated by crying episodes

Histology

- Majority of cases are in proliferative phase characterized by:
 - Unencapsulated cellular neoplasm with intralobular growth and replacement of salivary gland acini:
 - Despite replacement by a cellular proliferation, residual ducts and acini remain identifiable.
 - Near-solid masses of small capillaries consisting of epithelioid to plump endothelial cells and peripherally placed pericytes that invest endothelial cells
 - Distinct lobular architecture with lobules lacking encapsulation or fibrosis; lobules are separated by normal tissue elements and/or stroma of the involved site, and an intralobular central feeding artery may be identified.
 - Evidence of vascular differentiation (i.e., endothelial-lined lumina) may be limited:
 - Vascular lumina may be compressed and indistinct due to increased cellularity.
 - Evidence of vascular differentiation may best be identified at the periphery of the tumor.
 - Capillaries lined by two or more layers of endothelial cells, which have oval to spindle-shaped nuclei and eosinophilic granular cytoplasm
 - Mitoses frequently seen and may be numerous, but atypical mitoses are not present
 - Mast cells are present.
 - Neural pseudoinvasion, in which intralesional nerves show peri- and intraneural “invasion” by lesional capillaries:
 - Neural pseudoinvasion is a commonly identified and diagnostic feature as it is rarely seen in other benign vascular lesions.
 - Presence of neural pseudoinvasion and increased mitotic activity invasion do not render a diagnosis of malignancy and have no impact on behavior.
 - Histochemistry:
 - Reticulin stain delineates the outlines of the vascular sheath, within which is the endothelial cell proliferation.

Hemangioma, Capillary Type or Infantile (Juvenile) Hemangioma (Fig. 20-46)

Definition: Benign vascular tumor of infancy.

Synonyms: Benign (infantile) hemangioendothelioma; congenital or juvenile hemangioma; cellular hemangioma; immature capillary hemangioma

Clinical

- Common benign vascular tumor of infancy (affecting approximately 4% of children)
- Approximately 60% occur in head and neck.
 - Most common in the skin and subcutis
 - May occur in other locations, including salivary (parotid) glands
- Represents most common salivary gland tumor in pediatric population, accounting for greater than 90% of parotid gland tumors in children less than 1 year old
- More common in females than in males; may occur over a wide age range but most frequently seen in the first decade of life
- Almost exclusively involves parotid gland:
 - Occasionally the submandibular gland may be affected.
- Usually discovered at birth as a unilateral, compressible mass and bluish discoloration of overlying skin that may be accentuated during crying
 - Rapid enlargement and facial asymmetry may be seen, raising clinical suspicion for a malignancy
 - Extension to adjacent sites such as the hypopharynx may occur.
 - Ulceration of the overlying skin may occur.
- Generally appearing within weeks after birth, proliferate rapidly during the first year of life, and then spontaneously involute over a period of several years
- No association with:
 - Familial disorders such as von Hippel-Lindau syndrome or hereditary telangiectasia

Fig. 20-46. Infantile hemangioma involving the parotid gland.

A, The tumor is unencapsulated, multilobular, and cellular with intralobular growth. **B**, Variably sized blood-filled vascular channels replacing the salivary gland parenchyma; despite replacement by a cellular proliferation, residual ducts and acini remain identifiable. **C** and **D**, The tumor is composed of capillary-sized vessels, although many of the vascular lumina are compressed and indistinct due to increased cellularity. **E**, Neural pseudoinvasion (*arrowhead*) characterized by the presence of lesional capillaries located around nerves; this is a common finding and essentially diagnostic feature and is not indicative of malignancy. **F**, In addition to typical immunoreactivity for endothelial cell markers including CD31, CD34, and Factor 8–related antigen (not shown), lesional cells are characteristically reactive for glucose transporter 1 (GLUT1). Note the absence of expression in a nerve (*arrowhead*) surrounded by tumor, but GLUT1 expression is seen in peripherally situated normal perineurial cells, which is a consistent finding.

- Immunohistochemistry:
 - Lesional cells are immunoreactive for:
 - Glucose transporter protein isoform 1 (GLUT1)
 - Presence of GLUT1 reactivity (as well as other markers including Lewis Y antigen, Fc gamma receptor II, merosin, and others) is similar to that of the vasculature of the placenta demonstrating that infantile hemangiomas have a placenta-associated phenotype (**NOTE:** there is an absence of trophoblastic elements and villous architecture) in infantile hemangiomas
 - CD31, CD34, factor VIII–related antigen
- A minority (approximately 15%) of cases, vascular lesions may be relatively prominent at birth following a static or rapidly involuting course referred to as congenital nonprogressive hemangiomas, which are further subdivided into:
 - Rapidly involuting congenital hemangioma (RICH)
 - Noninvoluting congenital hemangioma (NICH)
- Congenital nonprogressive hemangiomas are histologically and immunophenotypically distinct from infantile hemangiomas:
 - Overall histology of lesional cellular proliferation similar to that of infantile hemangioma
 - In contrast to infantile hemangioma:
 - Tumor lobules are separated by dense fibrous tissue rather than normal tissue elements and/or stroma.
 - Sclerosis often extends into tumor lobules.
 - In cutaneous sites (most common location) there is skin atrophy with loss of dermal adnexal appendages.
 - Small foci of extramedullary hematopoiesis can be found.
 - Small arterial feeders can be found but typically lack intralobular central feeding artery.
 - Absence of neural pseudoinvasion
 - Absence of GLUT1 immunoreactivity as well as other markers that may suggest a placenta-associated phenotype
- With regression there is increased interstitial fibrosis; infarction secondary to thrombosis may be present.
- Immunohistochemistry:
 - Factor VIII–related antigen, *Ulex europaeus*, CD31, and CD34 positive
 - Glucose transporter protein isoform 1 (GLUT1) negative
- Tendency to occur in older children and adults
- Female predilection
- Primarily involve parotid gland
- Involve the extralobular connective tissue
- Characterized by presence of dilated, thin-walled vessels lined by flattened endothelial cells
- GLUT1 negative
- Do not regress and therefore requires complete surgical excision
- Lymphatic malformation (lymphangioma/cystic hygroma):
 - See Section 4, Neck, for more complete discussion.
 - Involvement of the parotid gland is less common than hemangiomas.
 - Most occur during childhood.
 - Histology is similar to lymphangiomas of more common locations, including the presence of variably sized, endothelial-lined spaces with or without intraluminal eosinophilic material, and surrounding collagenous stromal tissue
 - Complete surgical resection is the preferred treatment.
- Epithelioid hemangioma:
 - Formerly referred to as angiolymphoid hyperplasia with eosinophilia
 - Rarely involves salivary glands
 - See Section 7, Ear and Temporal Bone, for complete discussion.
- Angiosarcoma
- Kaposi sarcoma
- Hemangioendothelioma

Treatment and Prognosis

- Majority (75% to 90%) involute by 7 years of age; current recommendation in absence of an enlarging neoplasm with compromise of external ear canal and/or facial distortion, is delay surgery until an older age in the hope that the tumor will involute (spontaneously regress) over time.
 - Regression (involution) may occur in phases, initially slowly over the first 5 years of life and then with continuous regression through the first decade of life.
- Variable success has been reported with the use of corticosteroids, interferon, and compression therapy.
- (Oral) propranolol has replaced corticosteroids as preferred first-line therapy for management of infantile hemangiomas:
 - >94% of patients demonstrate response to treatment with size reduction, color changes, softened texture, and/or healing of ulceration.
 - Topical β -blocker timolol now an alternative to oral propranolol with watchful waiting for smaller infantile hemangiomas

Differential Diagnosis

- “Adult” hemangiomas:
 - May uncommonly be identified in salivary glands and are noted for:

- In presence of a rapidly enlarging lesion and/or disfiguring lesion complete surgical excision is preferred treatment with preservation of the facial nerve
 - Facial nerve in infants is in a more superficial location than in an older age; therefore surgical intervention in infancy may be associated with a greater incidence of damage to the facial nerve.
- Rarely, life-threatening growth may occur:
 - In this situation, preoperative combined radiation and chemotherapy may be indicated.
- Malignant transformation does not occur.

MALIGNANT NEOPLASMS

MUCOEPIDERMOID CARCINOMA (MEC)

(Figs. 20-47 through 20-56)

Definition: Malignant epithelial salivary gland neoplasm composed of a variable admixture of epidermoid, mucous, and intermediate cells.

- No benign counterpart, so the presence of a neoplasm with a marked cellular proliferation including requisite cell types is diagnostic for MEC, whether invasive or noninvasive

Clinical

- Most common malignant salivary gland tumor and second to pleomorphic adenoma as most frequent occurring neoplasm among all salivary gland tumors:
 - Represents approximately 30% of all malignant salivary gland tumors of major and minor salivary glands
 - Represents approximately 10% to 15% of all salivary gland neoplasms
- Slightly more common in women than in men; occurs over a wide age range but most frequently seen in the third to seventh decades of life with a mean age in the fifth decade of life:
 - In pediatric age group, MEC represents most common malignant salivary gland neoplasm, in particular in the second decade of life
- Occurs in major and minor salivary glands:
 - Slightly more than 50% occur in major salivary glands:
 - Among major glands, MEC by far is most common in parotid gland (45%) followed (much less frequently) by the submandibular gland (7%) and then sublingual gland (1%).
 - Most common minor salivary gland site of involvement is palate; additional minor salivary gland sites of occurrence in decreasing order include the buccal mucosa, lips (lower > upper), retromolar region, and tongue (base of tongue)
 - May occur in sinonasal tract and nasopharynx but are considered uncommon in these sites
- Clinical presentation in major glands may vary according to histologic grade:

- For low-grade and intermediate-grade MEC:
 - Slow-growing, solitary, painless mass
- For high-grade MEC:
 - Generally presents as rapidly enlarging, painful mass
- Additional symptomatology may include drainage from the ipsilateral ear, dysphagia, trismus, and facial paralysis.
- Two thirds of patients are asymptomatic.
- In the majority of patients, the duration of symptoms is within a 6-month period of time and average period is 1½ years.
 - Duration of symptoms may be greater, including years to decades
- In minor salivary glands symptoms may include pain, paresthesia, numbness, dysphagia.
- Etiology:
 - May be related to prior therapeutic radiotherapy with latent periods from the time of radiation to the head and neck to the development of a MEC of 7 to 32 years
 - Human papillomavirus (HPV):
 - Recent studies implicated HPV as a cause of MEC.
 - However, other studies using RNA in situ hybridization targeting high-risk HPV mRNA E6/E7 transcripts did not detect HPV in any MECs with or without MAML2 rearrangement (see below).
 - High-risk HPV does not appear to play any significant role in the development of MEC.

Pathology

Gross

- Unencapsulated or incompletely encapsulated, delineated to invasive, round to oval, predominantly solid, tan-white to pink mass measuring from less than 1 cm up to 12 cm in greatest dimension
- Cysts of variable size and prominence can be seen on sectioning of the tumor.
- Mucosal lesions (e.g., palate) may appear as bluish swelling underneath an intact mucosa and simulate the appearance of a mucocele; less often, mucosal

Fig. 20-47. Mucoepidermoid carcinoma.

A, Mucoepidermoid carcinoma of the parotid gland appearing as large ovoid mass at the angle of the mandible. The tumor was slowly enlarging and painless.

B, The resected and transected specimen revealing a poorly delineated solid and cystic neoplasm; cystic spaces were filled with clear to blood-tinged fluid. Histologically, the tumor proved to be low grade.

tumors may have a papillary or granular-appearing surface mucosa.

Fine-Needle Aspiration Biopsy (FNAB)

- Low-grade MEC:
 - Due to cystic nature aspirates may be acellular or hypocellular.

Fig. 20-48. Low-grade mucoepidermoid carcinoma, fine-needle aspiration biopsy.

The aspirate includes aggregates of cells, including epidermoid cells and scattered mucocytes; in addition, intermediate cells composed of bland cells with round to oval nuclei are present. These findings are diagnostic for low-grade mucoepidermoid carcinoma.

- Extracellular mucin may be the dominant finding:
 - May simulate the appearance of the mesenchymal component of pleomorphic adenoma but in contrast to mesenchymal component of pleomorphic adenomas, mucin:
 - Does not appear fibrillar
 - Does not stain as intensely
- Aggregates of cells, including epidermoid cells and mucocytes (mucus-secreting cells):
 - Epidermoid cells:
 - May appear relatively bland and result in the false impression of a nonneoplastic lesion or a benign neoplasm
 - Mucocytes:
 - Cells with distended cytoplasm and or perinuclear vacuoles due to presence of mucin
 - Mucin appears as intracytoplasmic, red granular material by Romanowsky staining.
 - Due to intracytoplasmic mucin the nucleus is eccentrically located.
 - In histologic sections mucocytes often represent a small percentage of the neoplastic cells, so they also tend to be limited by FNAB.
 - Predominantly cystic MECs often have a larger percentage of mucocytes, which translates into more readily identifiable mucocytes by FNAB.
- Intermediate cells appear as bland cells with round to oval nuclei with moderate amount of cytoplasm.

Fig. 20-49. Low-grade mucoepidermoid carcinoma, parotid gland.

A and B, Infiltrative cystic and solid neoplasm with readily identifiable and numerous mucocytes. **C and D,** At high magnification the neoplasm is comprised of an admixture of mucous cells, epidermoid cells characterized by polygonal shaped cells with eosinophilic cytoplasm and smaller more hyperchromatic-appearing intermediate cells with less cytoplasm. **E,** Extravasated mucin into fibroconnective tissue with associated inflammatory cell infiltrate and fibrosis. **F,** Epidermoid cells are diffusely and strongly p63 positive (nuclear staining) but mucocytes are negative for p63.

Fig. 20-50. Cystic low-grade mucoepidermoid carcinoma.

A, Encapsulated predominantly cystic lesion with area of more densely cellular intracystic proliferation with solid, papillary, and cribriform growth; focally, the tumor is separate from the parotid parenchyma (extreme right) but is infiltrative into the cyst wall (*arrow*), extending toward uninvolved parotid parenchyma. Although too difficult to appreciate at this magnification the remainder of the cyst is lined by a cuboidal epithelium lacking the overall diagnostic features for mucoepidermoid carcinoma. **B**, Another predominantly cystic encapsulated neoplasm with area of more densely cellular intracystic proliferation; tumor-associated lymphoid proliferation (TALP) is present (*arrows*) lying in between the cystic tumor and the surrounding parotid gland. The remainder of the cyst is lined by nondescript cuboidal epithelium focally exclusively comprised of mucous cells (*arrowhead*) lacking the overall diagnostic features for mucoepidermoid carcinoma. **C** and **D**, Proliferative areas comprised of an admixture of mucous cells, epidermoid cells, and intermediate cells diagnostic for mucoepidermoid carcinoma. In the presence of invasive growth the diagnosis is readily established but even in the absence of invasion, the presence of mucous cells, epidermoid cells, and intermediate cells would be diagnostic for mucoepidermoid carcinoma.

- High-grade MEC:
 - Readily identifiable as malignant but due to the scarcity of mucocytes even in tissue sections, a specific diagnosis of high-grade MEC may not be achievable.
 - In face of an aspirate with obviously high-grade malignant cytology, a definitive diagnosis of MEC is less important as the treatment for high-grade malignant epithelial tumors of the salivary glands should be similar.

Histology

- Characteristic features for all histologic grades (see below) include the presence mucous cells (mucocytes), epidermoid cells, and intermediate cells:
 - Mucous cells identified lining cystic spaces or admixed within nests or solid areas with epidermoid cells are large, ovoid, goblet, balloon-shaped, or columnar cells with distinct cell borders composed of pale-staining or

Fig. 20-51. Intermediate-grade mucoepidermoid carcinoma.

A, In comparison with low-grade tumors, intermediate-grade mucoepidermoid carcinomas are more solid and predominantly composed of epidermoid cells with residual cystic foci that include mucous cells (*upper right*). **B,** There is a shift in the ratio of mucous cells to epidermoid and intermediate cells with a larger percentage of the latter cells identified. **C,** In comparison to the low-grade cancers the cells in intermediate grade show a greater degree of nuclear pleomorphism as compared with low-grade mucoepidermoid carcinoma but significantly less nuclear pleomorphism, mitotic activity, and necrosis as compared with high-grade mucoepidermoid carcinoma.

- foamy-appearing cytoplasm with peripherally placed, small, dark staining nuclei:
 - Most numerous and readily identifiable in low-grade MEC
 - Less numerous but still readily identifiable in intermediate-grade MEC
 - Least numerous and not readily identified without histochemical staining (e.g., mucicarmine, PAS with diastase) in high-grade MEC
- Epidermoid cells form nests and/or solid areas have a pavement-like arrangement and are polygonal with vesicular nuclei and abundant eosinophilic cytoplasm.
 - In some examples epidermoid cell differentiation may be focal and limited in extent.
 - Individual cell keratinization and keratin pearl formation may be seen but are considered uncommon.
- Keratin (squamous) pearls, extensive keratinization, and intercellular bridges do not predominate.
- Foci of keratinization (individual cell and/or keratin pearl formation) may occur in inflamed tumors.
- Absence of keratin (squamous) pearls, extensive keratinization, and intercellular bridges assist in separating mucoepidermoid carcinoma from such tumors as adenosquamous carcinoma.
- Intermediate cells include both small basal cells and larger polygonal cells appearing in clusters of solid sheets or scattered and admixed with the other cell types:
 - Basal cells: characterized by the presence of round to oval, small, dark-staining nuclei and scanty, eosinophilic cytoplasm

Fig. 20-52. Mucoepidermoid carcinoma.

High-grade mucoepidermoid carcinoma appearing as a large, ulcerating and necrotic hard palate mass.

- Larger polygonal cells: round to ovoid cells with vesicular chromatin and more abundant cytoplasm
- Transitional areas from smaller basal cells to larger polygonal cells can be seen.
- Other cell types that may be seen include:
 - Clear cells composed of round to oval cells with distinct cell borders, peripherally placed, small, dark nuclei and their hallmark clear cytoplasm:
 - May range from very focally identified to predominating (i.e., clear cell variant, see below)
 - Oncocytic cells characterized by presence of a brightly eosinophilic and granular-appearing cytoplasm
 - Often can be seen focally and occasionally predominate (i.e., oncocytic variant, see below)
 - Columnar cells can be seen lining cysts and duct-like structures and tend to be less numerous than mucous cells.

Fig. 20-53. High-grade mucoepidermoid carcinoma.

A, Neoplastic proliferation with solid growth composed of epithelial cells. **B**, Marked nuclear pleomorphism with increased mitotic activity. **C**, Rare mucocytes (*arrow*) may be seen by light microscopy. **D**, Intracytoplasmic mucicarmine positive material.

Fig. 20-54. Clear cell variant of mucoepidermoid carcinoma.

A, Cellular components predominated by cells with clear cytoplasm with admixed foci of epidermoid cells (*arrows*) and mucous cells (*arrowheads*). **B,** Higher magnification shows predominant clear cell component with identifiable mucocytes. **C,** Mucocytes show the presence of intracytoplasmic mucin-positive material but the clear cells are mucicarmine negative. The clear cells contain glycogen as evidence of the presence of diastase-sensitive, PAS-positive material (not shown).

- Spindle-shaped cells may focally be present.
- Rarely pigmentation (melanin-containing) cells may be present.
- Tumors may be encapsulated or unencapsulated with or without invasion:
 - Diagnosis of MEC can be established even in the absence of invasive growth based on identifying the constituent cell types (see above):
 - Benign neoplastic counterpart to MEC composed of mucous cells, intermediate cells, and epidermoid cells not known to exist
 - Encapsulated (noninvasive) MECs tend to be histologically lower grade.
 - Benign nonneoplastic lesions as well as benign neoplasms may be cystic and composed of
 - varying cell types, including mucocytes and epidermoid cells:
 - Degree of cellular proliferation is much greater in MEC than in these other lesions.
 - Intermediate cells are typically absent in these nonmalignant lesions but may also be difficult to appreciate in MECs
- Growth patterns include predominantly cystic, predominantly solid, or admixture of cystic and solid:
 - Additional growth patterns may include papillary, glandular, or duct-like:
 - Cysts are lined by mucous, columnar, and epidermoid cells.
 - Origin from duct epithelium may occasionally be identified.

Fig. 20-55. Oncocytic cell variant of mucoepidermoid carcinoma.

A, The tumor is predominated by cells with oncocytic cytoplasmic change but scattered identifiable mucous cells are present. **B**, The mucocytes show the presence of intracytoplasmic diastase-resistant, PAS-positive material. The presence of mucocytes usually would differentiate oncocytic mucoepidermoid carcinoma from other oncocytic lesions/neoplasms (e.g., oncocytoma, oncocytic carcinoma). Residual foci of usual mucoepidermoid carcinoma, including epidermoid cells, mucous cells, and intermediate cells (which may or may not be present) and/or diffuse p63 reactivity would confirm a diagnosis of oncocytic MEC.

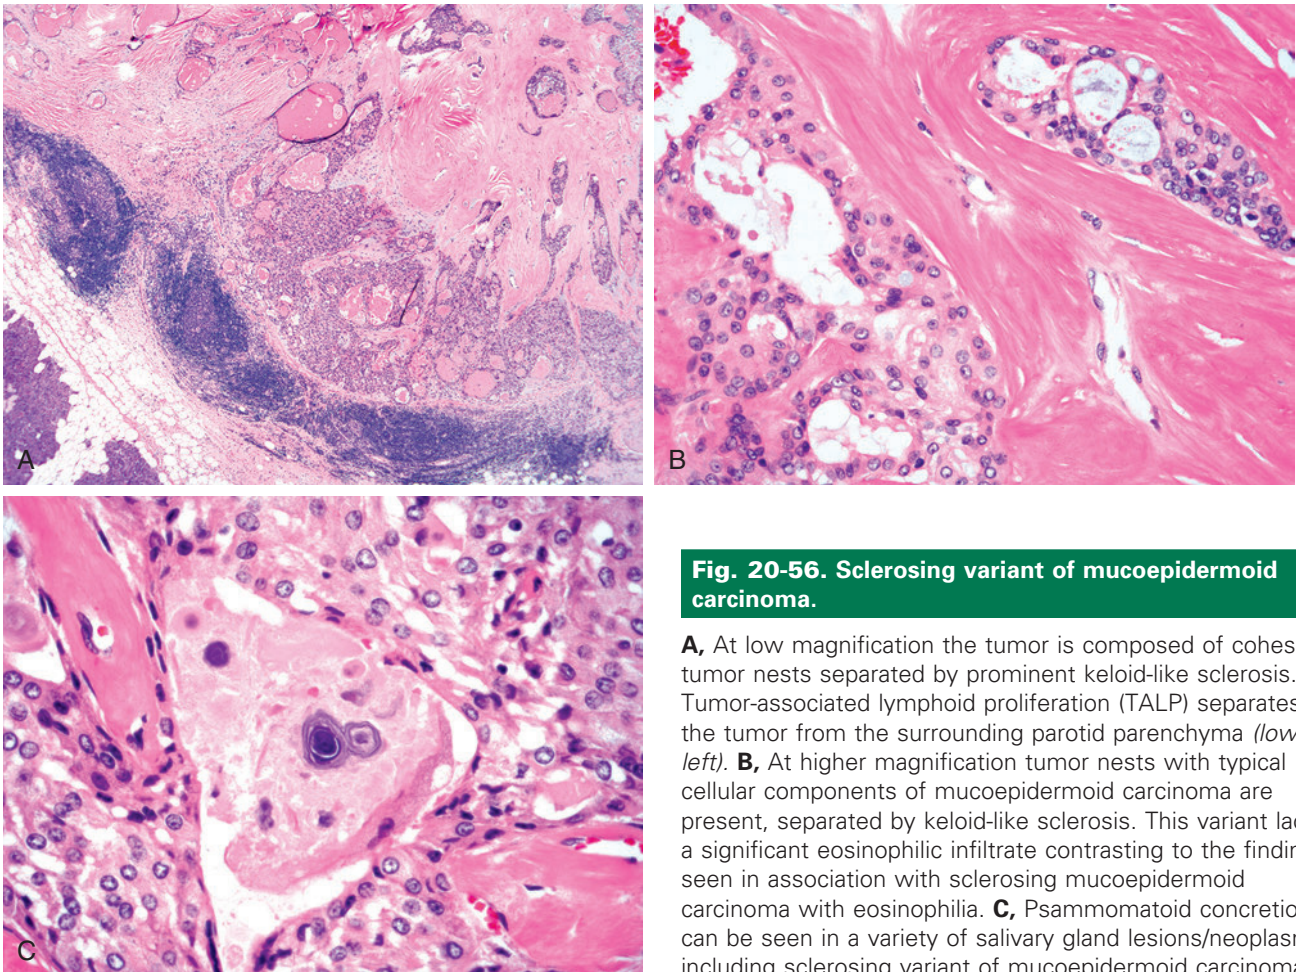

Fig. 20-56. Sclerosing variant of mucoepidermoid carcinoma.

A, At low magnification the tumor is composed of cohesive tumor nests separated by prominent keloid-like sclerosis. Tumor-associated lymphoid proliferation (TALP) separates the tumor from the surrounding parotid parenchyma (*lower left*). **B**, At higher magnification tumor nests with typical cellular components of mucoepidermoid carcinoma are present, separated by keloid-like sclerosis. This variant lacks a significant eosinophilic infiltrate contrasting to the findings seen in association with sclerosing mucoepidermoid carcinoma with eosinophilia. **C**, Psammomatoid concretions can be seen in a variety of salivary gland lesions/neoplasm, including sclerosing variant of mucoepidermoid carcinoma.

- Stroma is often fibrous and may be sclerotic/hyalinized:
 - Tumors with extensive stromal sclerosis have been referred to as sclerosing MEC (see below).
- Prominent lymphoid tissue with or without lymphoid follicles may be evident:
 - Referred to as tumor-associated lymphoid proliferation (TALP)
 - TALP may lead to mistaken interpretations of primary tumors as nodal metastasis or benign lymphoepithelial lesion.
 - Primary salivary gland tumors including MEC may originate from salivary gland parenchyma incorporated within peri- and intranodal lymph nodes; as such, TALP must be differentiated from tumor within a lymph node.
 - Presence or absence of a subcapsular sinus will differentiate bona fide lymph node parenchyma (with subcapsular sinuses) from non-lymph node parenchyma (without subcapsular sinuses).
- Intraluminal mucus can be seen in cysts and/or gland-like structures:
 - Extravasation of mucin appearing as extracellular mucous pools or “cysts” may be seen.
- Cellular pleomorphism, mitoses, necrosis, and hemorrhage are generally absent:
 - Such findings when identified are more common in histologically higher-grade tumors.
- A variable degree of local invasion may be seen:
 - Invasion into surrounding cyst wall, fibroconnective tissue, residual nonneoplastic salivary gland parenchyma often is present
 - Such invasive growth essentially similar irrespective of histologic grade

- Perineural and/or lymph-vascular invasion may be identified:
 - More commonly seen in histologically higher-grade MEC

Histologic (Microscopic) Grading

- Three histologic grades recognized:
 - Low grade
 - Intermediate grade
 - High grade
- Basis for histologic grading into low, intermediate, and high categories dependent on:
 - Architectural growth pattern
 - Cellular components
 - Cytomorphology
- Microscopic grading remains subject of debate
- Criteria for histologic grading include (single or in combination):
 - Proportion of the tumor composed of cystic spaces relative to solid growth
 - Proportion of cell types
 - Degree of maturation of cell types
 - Mitotic rate
 - Extent of invasiveness, including pattern of invasion, neurotropism, and vascular space invasion
 - Presence of necrosis
- A quantitative grading system based on specific histologic features suggested (Table 20-5):
 - According to Armed Forces Institute of Pathology (AFIP) grading scheme:
 - 0 to 4 are considered low grade (Grade I)
 - 5 to 6 are considered intermediate grade (Grade II)
 - 7 or more are considered high grade (Grade III)

TABLE 20-5 Mucoepidermoid Carcinoma: Microscopic Grading

Feature	Grade	Tumor Grade	Point Score
<i>Auclair et al[*]; Goode et al[†]</i>			
Intracystic component less than 20%	2	Low-grade	0-4
Neural invasion	2	Intermediate-grade	5-6
Necrosis	3	High-grade	7 or more
Four or more mitoses	3		
Anaplasia	4		
<i>Brandwein et al[‡]</i>			
Intracystic component less than 25%	2	Low-grade	0
Tumor front invades in small nests and islands	2	Intermediate-grade	2-3
Pronounced nuclear atypia	2	High-grade	4 or more
Lymph-vascular invasion	3		
Bony invasion	3		
Four or more mitoses	3		
Perineural invasion	3		
Necrosis	3		

*Cancer 69:2021-2030, 1992.

†Cancer 82:1217-1224, 1998.

‡Am J Surg Pathol 25:835-845, 2001.

- According to Brandwein et al grading scheme:
 - 0 are considered low grade (Grade I)
 - 2 to 3 are considered intermediate grade (Grade II)
 - 4 or more are considered high grade (Grade III)
- Most useful features for histologic grading, particularly in predicting high-grade tumors, include:
 - Intracystic component of less than 20% (predominantly solid growth)
 - Four or more mitotic figures per 10 high-power fields
 - Cellular anaplasia, necrosis, neural invasion, angioinvasion, and osseous invasion
- With exceptions, typical histologic features associated with different histologic grades include:
 - Low grade:
 - Numerous cystic spaces
 - All three cell types identified including numerous/readily identifiable mucocytes
 - Overall absence of nuclear pleomorphism, increased mitotic activity, and necrosis
 - Absence of perineural invasion
 - Intermediate grade:
 - Predominantly solid but still cystic
 - Composed of all three cell types perhaps with greater percentage of epidermoid cells and less percentage of mucocytes
 - Greater degree of nuclear pleomorphism as compared to low-grade MEC but significantly less nuclear pleomorphism, mitotic activity, and necrosis as compared with high-grade MEC
 - High grade:
 - Diffuse sheet-like or solid growth
 - Cystic spaces make up less than 20% of the tumor or
 - Cellular anaplasia with marked nuclear pleomorphism, increased mitotic activity, including atypical mitoses and necrosis
 - Limited identifiable mucocytes
 - Tend to be extensively infiltrative, including perineural invasion and lymph-vascular invasion
- Percentage of cell types do not necessarily correlate with behavior.
- Histochemistry:
 - Mucocytes:
 - Intracytoplasmic diastase-resistant, PAS-positive, and mucicarmine-positive staining
 - Gland-like spaces:
 - Intraluminal diastase-resistant, PAS-positive, and mucicarmine-positive staining
 - Epidermoid cells may be faintly PAS positive but are mucicarmine negative.
 - Intermediate cells and clear cells show no staining with either PAS or mucicarmine.
- Immunohistochemistry:
 - Cytokeratin (pancytokeratin, CK5/6, others) and epithelial membrane antigen (EMA) positive
 - p63 positive (strong nuclear staining)
 - S100 protein, calponin, glial fibrillary acidic protein, muscle-specific actin, and carcinoembryonic antigen are at best variably positive and more often negative.
 - May be mammaglobin positive but typically focal lacking moderate to strong staining in significant proportion of cells (i.e., more than 25%)
 - GATA3 (nuclear) staining may be present but when present is focal rather than diffuse:
 - Diffuse GATA3 staining in salivary gland neoplasm typically limited to salivary duct carcinoma and mammary analogue secretory carcinoma
 - Androgen receptor negative
 - *HER-2* overexpression typically absent
 - Sox10 negative
 - Express membrane-bound mucins, including:
 - MUC1, MUC4, MUC5AC, and MUC5B
- Electron microscopy:
 - Presence of two cell types, including luminal cells with microvilli, goblet cell formation, and mucus secretion, and the nonluminal intermediate cells felt to represent the counterpart of the modified myoepithelial cells seen in mixed tumors
- Cytogenetics and molecular biology:
 - Mucoepidermoid carcinoma translocated 1 (*MECT1*) and mastermind-like gene family (*MAML2*) translocation located at chromosome 19p13 and 11q21 represent most frequent genetic alteration
 - Detected by RT-PCR or fluorescence in situ hybridization
 - Identified in large proportion of MEC
 - Present in 66% MEC
 - 100% non-MEC negative for translocation
 - Low- to intermediate-grade MEC higher frequency of translocation (75%) than high-grade MEC (46%)
 - *CRTC1* (CREB-regulated transcription coactivator-1) used in place of *MECT1*
 - Presence of *CRTC1-MAML2* translocation identified as useful adjunct to histologic scoring as prognostic indicator:
 - Low-grade, fusion-positive MEC with no or few genomic imbalances and favorable prognosis
 - High-grade, fusion-positive MEC with multiple genomic imbalances and unfavorable prognosis
 - Heterogeneous group of high-grade, fusion-negative adenocarcinomas with multiple

genomic imbalances and unfavorable outcome

- A less common gene fusion includes *CRTC3* (CREB-regulated transcription coactivator-3) on chromosome 15q26 and *MAML2*:
 - Associated with favorable prognosis
- *PLAG1* translocation negative
- *ETV6* translocation negative

Histologic Variants of MEC

Clear Cell Variant

- Characterized by predominance of large cells with clear-appearing cytoplasm and discrete cell membranes
- Residual foci of usual or classic MEC typically present including mucocytes containing epithelial mucin
- Typically histologically low-grade lacking significant nuclear pleomorphism, increased mitotic activity, and necrosis
- Histochemical stains show the presence of intracytoplasmic diastase-sensitive, PAS-positive material indicative of glycogen
- Mucicarmine negative
- Cytokeratins and p63 positive
- *EWSR1-ATF1* gene fusion identified in clear cell carcinoma of salivary glands is negative in clear cell variant of MEC.
- More common variant relative to palate MEC

Oncocytic Variant

- Characterized by cells with abundant granular eosinophilic cytoplasm (i.e., oncocytes) but percentage of oncocytic cells necessary for diagnosis not well defined
- Predominantly solid growth pattern
- Scattered mucocytes containing epithelial mucin (mucicarmine and/or diastase-resistant, PAS-positive) identified:
 - Presence of mucocytes usually but not always differentiates oncocytic MEC from other oncocytic lesions/neoplasms that may rarely contain such cells, including:
 - Oncocytosis, oncocytoma, oncocytic carcinoma
 - Presence of foci of classic MEC and/or diffuse p63 reactivity assist in confirming diagnosis of oncocytic MEC
- Typically lack significant nuclear pleomorphism, increased mitotic activity, and necrosis
- Residual foci of usual or classic MEC may or may not be present.
- *CRTC1-MAML2* translocation present
- In spite of solid growth, this variant is histologically (and biologically) low grade:
 - Single reported case purportedly of a high-grade oncocytic MEC

- Predominantly but not exclusively a parotid gland neoplasm:
 - May occur in submandibular gland and minor salivary glands

Sclerosing Variant

- Histologically typical MEC albeit with prominent central (keloid-like) sclerosis
 - May be paucicellular in areas of sclerosis with more typically neoplastic foci along periphery
- Associated lymphoplasmacytic infiltrate located along periphery of the neoplasm
- Absence of significant eosinophilic infiltrate
- Absolute number of IgG4 plasma cells as well as proportion of IgG4/IgG plasma cells increased in sclerosing MEC as compared with the regular type
- Possible relationship to IgG4-related diseases remains to be determined.

Sclerosing MEC with Eosinophilia

- Rare variant and may be related to sclerosing variant without eosinophilia
- Histologically composed of epithelial nests that may include mucin-containing cells embedded in a sclerotic stroma
- Fibrosclerotic stroma densely infiltrated by chronic inflammatory (lymphoplasmacytic) cells and eosinophils
- Lesional cells may appear squamoid including presence of keratinization.
- Inflammatory infiltrate and stromal fibrosclerosis may also be seen in non-neoplastic salivary gland tissue adjacent to tumor.
- Immunohistochemically, many plasma cells may be IgG4-positive.
- Postoperative serum IgG4 level may be elevated.
- Possible relationship to IgG4-related diseases remains to be determined.

Differential Diagnosis (Table 20-6)

- Low and intermediate MEC:
 - Necrotizing sialometaplasia
 - Non-neoplastic true epithelial cystic lesions, including:
 - Lymphoepithelial cyst and salivary duct cyst
 - Pleomorphic adenoma with squamous and mucous cell metaplasia
 - Metaplastic Warthin tumor
 - Sclerosing polycystic adenosis
 - Cystadenoma and cystadenocarcinoma
 - Acinic cell adenocarcinoma
 - Mammary analogue secretory carcinoma
- High-grade MEC:
 - Conventional squamous cell carcinoma (primary or secondary)
 - Adenosquamous carcinoma

TABLE 20-6 Mucoepidermoid Carcinoma: Differential Diagnosis

	MEC, Low Grade	SCC	NS
Architecture/growth	Haphazard, infiltrative growth; may be encapsulated	Haphazard, infiltrative growth	Retention of lobular architecture
Cellular components	Admixture of mucous, intermediate ("basaloid"), and epidermoid cells; bland cytology; irregular cell nests	Nests and cords of squamous cells characterized by keratinization and intercellular bridges with irregular outlines and variable amount of cytologic atypia; may entrap residual glands but the tumor itself contains no mucin	Smooth round to oval nests of metaplastic squamous epithelium with bland cytology; may show residual ductal lumina with mucous cells
Cyst formation	Present (prominent component)	Absent	Absent
Surface epithelium	Uninvolved; not connected with tumor	Often dysplastic and/or in direct continuity with the carcinoma; may be ulcerated	May show PEH; usually not connected with NS
Extravasated mucin	May be present	Absent	May be present
Necrosis	Absent	May show tumor necrosis	Lobular necrosis of salivary gland acini
Inflammation	May be prominent with mucin extravasation	May be present; associated desmoplasia	May be prominent
Cytogenetics	<i>CRTC1-MAML2</i> translocation	None known	None known

MEC, Mucoepidermoid carcinoma; NS, necrotizing sialometaplasia; PEH, pseudoepitheliomatous hyperplasia; SCC, squamous cell carcinoma.

- Salivary duct carcinoma
- Cystadenoma and cystadenocarcinoma
- Clear cell variant MEC:
 - Clear cell carcinoma
 - Metastatic renal cell carcinoma
- Oncocytic variant MEC:
 - Oncocytosis
 - Oncocytoma
 - Oncocytic carcinoma

Treatment and Prognosis

- Therapy is primarily surgical:
 - Stages I and II treated by:
 - Wide local surgical excision with preservation of the facial nerve (for parotid neoplasms)
 - Patients with partial parotidectomies with clear surgical margins fare as well as patients who undergo total parotidectomies.
 - May recur locally if incompletely excised but metastatic disease infrequently occurs
 - Submandibular gland tumors should be treated by complete surgical glandectomy.
 - Palatal-based lesions that are small (less than 2 cm) and do not involve bone can be managed by wide local excision down to the periosteum with at least 1-cm clear lateral surgical margins:
 - Block excision of underlying bone is done if there is evidence of bone destruction.
 - Regional nodal metastasis for low- and intermediate-grade MECs of major (except submandibular gland) and minor salivary glands considered uncommon not necessarily warranting elective neck dissection unless clinically suspicious neck disease
 - Likelihood of occult cervical lymph node metastasis for patients with clinical N0 salivary gland carcinoma of major and minor salivary glands low and driven predominantly by histologic subtype; reported incidence of 21% (25 of 110):
 - Highest among patients with high-grade MEC and adenocarcinoma, high-grade, not otherwise specified
 - Most common site of cervical lymph node metastasis level II > level III > level IB
 - Adjuvant radiotherapy does not offer any advantage over complete surgical extirpation with free surgical margins for low-grade and intermediate-grade tumors:
 - Radiation may be useful in the local control of disease if residual tumor is found at the surgical margins in a patient no longer amenable to surgery.
 - Due to worse prognosis associated with submandibular gland tumors, combined surgery and radiotherapy have been advocated as the initial planned treatment.
 - High-grade MEC:
 - Treatment depends on clinical stage but in general wide block surgical excision is

preferred treatment, which may necessitate sacrifice of the facial nerve (parotid gland tumors) or the hypoglossal and lingual nerves (submandibular tumors).

- Radical palatotomy is required for palatal-based large lesions with involvement of bone.
- Associated with high rates of recurrence and metastasis and owing to frequency of metastasis to regional lymph nodes, neck dissections are usually included in the surgical management.
- Adjuvant postoperative radiotherapy is advocated for patients with high-stage disease (Stages III and IV), especially for high-grade tumors with tumor margins involved.
- Role of chemotherapy in the treatment of salivary gland carcinomas remains speculative.
- Prognosis:
 - In general, low-stage and/or low-grade and intermediate-grade tumors have excellent prognosis with approximately 90% 5-year survival rates.
 - In children (who have predominantly histologic low-grade and/or low-stage tumors), 5-year overall survival of 98% and 10-year overall survival of 94% reported
 - No difference in outcome reported between low and intermediate grade in all grading schemes
 - Overall 40% 5-year survival rates for high-stage and/or high-grade MEC
- Factors influencing prognosis:
 - Histologic grade influential in prognosis (Table 20-7), with the exception of submandibular gland involvement, which is not felt to be as reliable a predictor of behavior as compared with other salivary gland sites

- Mortality rates based on histologic grade include:
 - For AFIP, mortality rates based on their grading scheme include:
 - Grade I: 0
 - Grade II: 5%
 - Grade III: 46%
 - For Brandwein et al, mortality rates based on their grading scheme include:
 - Grade I: 0
 - Grade II: 5%
 - Grade III: 65%
- *CRTC1-MAML2* fusion-positive MEC, regardless of grade, manifest a more stable genome and better clinical behavior.
- Negative prognostic factors include:
 - High histologic grade
 - Advanced clinical stage
 - Perineural invasion
 - Positive surgical margins
 - Extraparenchymal extension
 - Submandibular location
 - Nodal metastases
 - Distant metastases
 - *CRTC1-MAML2* fusion-negative cases represent distinctly different pathway characterized by marked genomic instability and relatively aggressive tumors
 - Aneuploidy, high proliferation indices (>10%)
 - Increase expression of MUC1 (>75%)

ACINIC CELL CARCINOMA

(Figs. 20-57 through 20-61)

Definition: Malignant epithelial salivary gland neoplasm characterized by a variety of histologic growth patterns and tendency for neoplastic cells to recapitulate appearance of normal serous acinous cells characterized by the presence of cytoplasmic (zymogen type) secretory granules.

Clinical

- Represents approximately 18% of all malignant salivary gland neoplasms and 6.5% of all salivary gland neoplasms
- Slightly more common in women than in men; wide age range from children to older adults with a peak incidence in the seventh decade of life:
 - Approximately 4% occur in children.
 - In children, the majority of cases occurs in the second decade of life.
 - Represents second most common malignant epithelial neoplasm to occur in children; mucoepidermoid carcinoma is most common pediatric malignant salivary gland neoplasm
- Majority of cases (more than 80%) arise in the parotid gland:

TABLE 20-7 Mucoepidermoid Carcinoma: Microscopic Grading and Prognosis

Microscopic Grade	Percent Dead of Disease [§] or Prognosis
<i>Auclair et al</i> [*] ; <i>Goode et al</i> [†]	
Low grade	0
Intermediate grade	5
High grade	46
<i>Brandwein et al</i> [‡]	
Low grade	No recurrences, metastases, or deaths
Intermediate grade	Local recurrence 30%; nodal metastasis 18%; 5% dead of disease
High grade	Local recurrence 70%; nodal metastasis 63%; 65% dead of disease

^{*}Cancer 69:2021-2030, 1992.

[†]Cancer 82:1217-1224, 1998.

[‡]Am J Surg Pathol 25:835-845, 2001.

[§]Reflects cumulative statistics from Auclair et al and Goode et al studies, including major and minor salivary glands.

Fig. 20-57. Cytology of acinic cell adenocarcinoma.

Acinic cell adenocarcinoma of the parotid, fine-needle aspiration biopsy. Cellular aspirate composed of serous acinar cells characterized by large cells with round, relatively uniform, centrally situated nuclei, inconspicuous to conspicuous nucleoli, and abundant, granular-appearing cytoplasm.

- Uncommon but may also be identified in the submandibular and sublingual glands
- May also occur in all minor salivary glands, especially those of intraoral sites:
 - Most common intraoral sites are the buccal mucosa and upper lip.

NOTE: Prior to diagnosing acinic cell carcinoma of a nonparotid gland site, exclusion of other diagnostic considerations, especially mammary analogue secretory carcinoma (MASC), is mandatory as many acinic cell carcinomas of nonparotid gland sites have been reclassified as another tumor type (e.g., MASC).

- Bilateral parotid gland, and less often submandibular gland, involvement may uncommonly occur (approximately 3% of cases):
 - Represents most common malignant salivary gland neoplasm to present with bilateral disease
- Most common presentation is that of a slow-growing, solitary mass without fixation to surrounding structures:
 - Associated pain may or may not be present.
 - Facial paralysis may occur in up to 10% of patients.
 - Fixation to surrounding structures may uncommonly occur.
 - Duration of symptoms typically is less than a year but may occur from several years to decades.
- Thought to arise from distal (terminal) portions of the salivary duct system, specifically the intercalated duct reserve/stem cells
- Etiology:
 - No known causes

Pathology

Gross

- Well-demarcated and/or encapsulated, round or multilobulated, soft to rubbery, tan-gray to yellow or pink mass usually measuring from 1 to 3 cm in greatest diameter but occasionally may reach sizes up to 13 cm
- Most neoplasms have homogeneous appearance but may be cystic and hemorrhagic.
- Recurrent neoplasms are less well demarcated and tend to be multinodular in appearance.

Fine-Needle Aspiration Biopsy

- Aspirates tend to be cellular except for the papillary-cystic and follicular variants, which may have low numbers of serous acinar cells.
- Cytologic diagnosis rests on presence of identifying serous acinar cells characterized by:
 - Large cells with round, relatively uniform dark-staining nuclei, inconspicuous to conspicuous nucleoli, and abundant, granular-appearing cytoplasm
 - Appearance in clusters resembling normal acini or as individual cells
 - Presence of stripped or naked nuclei may be present in the background and may be mistaken for lymphocytes.
 - Centrally situated nuclei lacking polarity, which contrasts to normal (non-neoplastic) serous acinar cells, in which the cells have basally oriented nuclei
- An associated benign lymphocytic cell infiltrate may be apparent in aspirates.
- Psammomatoid concretions may be identified in aspirates.
- Serous acinar cells may be mistaken for oncocytic cells and in conjunction with a lymphocytic cell infiltrate may be misdiagnosed as Warthin tumor.

Histology

- May be circumscribed, encapsulated, or infiltrative
- Characterized by a variety of growth patterns including solid, microcystic, papillary-cystic, and follicular:
 - Solid and microcystic:
 - Most common patterns and often seen in association with each other
 - Solid growth consists of sheets or aggregates of tumor cells in lobules or organoid arrangement
 - Microcystic consists of numerous small cystic spaces.
 - Microcysts may appear as empty spaces or may contain eosinophilic to basophilic material.

Fig. 20-58. Acinic cell carcinoma.

Multiple growth patterns can be seen from case to case and even within a single case including (A) solid and focally cystic; (B) microcystic; (C) papillary-cystic; and (D) follicular. E, A coexisting lymphoid cell infiltrate referred to as tumor-associated lymphoid proliferation (TALP) is often but not uniquely seen in association with acinic cell carcinoma. The presence of TALP may suggest tumor within a lymph node but the absence of subcapsular sinuses would allow discrimination from tumor within a (periparotid) lymph node. F, The epithelial proliferation may appear to be "floating" in cystic spaces with bulging of the epithelial cells into the lumen in an uneven manner resulting in a hobnail or "tombstone row" appearance.

Fig. 20-59. Acinic cell carcinoma.

The cytomorphic features in acinic cell carcinoma include (**A** and **B**) polyhedral cells with eccentrically placed nuclei and characteristic abundant basophilic granular cytoplasm with admixed vacuolated cells characterized by clear cytoplasmic vacuoles; (**C**) intercalated duct-like cells characterized by amphophilic cytoplasm and sparse to absent basophilic granules; (**D**) nonspecific glandular cells are round to polygonal shaped with round nuclei, amphophilic to eosinophilic cytoplasm and indistinct or ill-defined cell borders; (**E**) DOG1 immunoreactivity is positive in acinic cell carcinoma showing complex mixture of intense apical membranous, complete membranous and cytoplasmic staining.

Fig. 20-60. Acinic cell carcinoma.

Psammoma bodies can be identified but are not unique to acinic cell carcinoma, being present in other salivary gland neoplasms.

- Papillary-cystic and follicular:
 - Less common patterns (papillary/cystic more common than follicular)
 - Papillary-cystic consists of variable-sized cystic spaces associated with papillary projections supported by a thin fibrovascular core:
 - Epithelial proliferation may appear to be “floating” in cystic spaces
 - Epithelial cells may bulge into the lumen in an uneven manner, resulting in a “tombstone row” appearance.
 - Follicular pattern resembles thyroid parenchyma with epithelial-lined lumens containing eosinophilic proteinaceous material lined by cuboidal to columnar cells.
- Cytologic variation present from case to case and even within a given case, including presence of:
 - Acinic or acinar cells:
 - These cells are diagnostic (pathognomonic).
 - Polyhedral with small, dark, eccentrically placed nuclei and characteristic abundant basophilic cytoplasm with cytoplasmic (zymogen-like secretory) granules; zymogen-like secretory granules define these as acinar cells.
 - These cells may predominate in well-differentiated tumors, but in any given tumor they may represent a minority of neoplastic cells.
 - May be vacuolated that in contrast to vacuolated (nonacinar) cells retain their cytoplasmic diastase-resistant, PAS-positivity
 - Intercalated duct-like cells:
 - Cuboidal or columnar with centrally placed small dark nuclei and eosinophilic to amphophilic cytoplasm
 - Found in majority of tumors but usually represent a smaller percentage of cellular components
 - May predominate in about one third of cases
 - Vacuolated cells:
 - Contain clear cytoplasmic vacuole, which may be numerous, vary in size, and distend the cell membranes.
 - These cells are more commonly seen in acinic cell adenocarcinoma than in other salivary gland neoplasms but are identified in other salivary gland neoplasms and are not in and of themselves diagnostic for acinic cell carcinoma.
 - Clear cells:
 - Round to oval cells with distinct cell borders, peripherally placed, small, dark nuclei and hallmark clear cytoplasm
 - Result from fixation and/or tissue processing
 - Considered an uncommon cell type in acinar cell carcinoma
 - Likely “pure” clear cell variant of acinic cell carcinoma does not exist.
 - Nonspecific glandular cells:
 - Lack specific features seen in other cell types
 - Are round to polygonal with round nuclei, amphophilic to eosinophilic cytoplasm, and indistinct or ill-defined cell borders
 - Tend to be more cellular and pleomorphic with a syncytial growth
- Although a single growth pattern and cell type may predominate in any given tumor, it is not uncommon to see multiple growth patterns and cell types in a single tumor.
- No established histologic grading system associated with acinic cell carcinomas

Fig. 20-61. High-grade transformation (dedifferentiation) of acinic cell carcinoma.

A, Infiltrative parotid gland tumor with trabecular and solid growth; in areas residual foci of (differentiated) acinic cell carcinoma characterized by **(B)** microcystic growth pattern and **(C)** cells with basophilic granular cytoplasm were seen; **(D)** transformation to high-grade undifferentiated carcinoma; **(E)** invasive growth with perineural invasion.

- Cellular pleomorphism and mitotic activity are typically absent.
 - Typically, stroma is scant but occasionally may be dense and hyalinized.
 - A prominent lymphoid component with germinal centers representing tumor-associated lymphoid proliferation (TALP) present in many tumors.
 - Occasionally, psammomatoid concretions similar to those seen in thyroid papillary carcinoma may be present.
 - Hemorrhage may be present including in connective tissue and within epithelial cells:
 - Intracytoplasmic hemosiderin pigment appears finely granular.
 - Most often seen in association with the papillary-cystic growth pattern
 - Not uniquely seen in acinic cell carcinoma
 - Diagnosis can be rendered even in the absence of invasive growth based on architecture, cytomorphology, and immunohistochemical staining (see below) as there is no known benign counterpart to acinic cell carcinoma.
 - Marked reactive and degenerative may be seen occurring spontaneously or secondary to prior traumatic event such as a fine-needle aspiration biopsy that may include:
 - Infarction
 - Cystic degeneration
 - Hemorrhage including recent and remote with hemosiderin deposition in lesional cells, fibroconnective tissue, and histiocytes
 - Mixed chronic inflammatory cell infiltrate
 - Cholesterol granuloma formation
 - Lipogranulomatous reaction
 - Rarely, amyloid deposition may be present
 - Histochemistry:
 - Acinar cells and intercalated duct cells:
 - Diastase-resistant, PAS-positive cytoplasmic granules
 - Mucicarmine and alcian blue typically negative but may be weakly positive:
 - Presence of some intracytoplasmic mucicarmophilic material can be seen and does not exclude the diagnosis.
 - Vacuolated cells:
 - PAS negative
 - Mucicarmine and alcian blue negative
 - Clear cells:
 - PAS negative
 - Mucicarmine and alcian blue negative
 - Nonspecific glandular cells:
 - PAS negative
 - Mucicarmine and alcian blue negative
 - Microcystic pattern:
 - Eosinophilic to basophilic material may stain for PAS and mucicarmine.
 - Papillary-cystic pattern:
 - Intraluminal and extracellular PAS-positive and mucicarmine-positive material may be present.
 - Follicular pattern:
 - Luminal material may be PAS positive and weakly mucicarmine positive.
- Immunohistochemistry:
 - Discovered on GIST-1 (DOG-1) positive:
 - Relative to salivary gland lesions/neoplasms considered marker of acinar cells and to a lesser extent intercalated duct differentiation
 - All acinic cell carcinomas reported to be DOG-1 positive
 - Demonstrates complex mixture of intense (3+) apical membranous, cytoplasmic, and complete membranous staining:
 - Strong staining used to support diagnosis of acinic cell carcinoma
 - Other tumor types that may express DOG-1 include adenoid cystic carcinoma and epithelial-myoepithelial carcinoma, showing distinctive combined apical ductal and membranous/cytoplasmic myoepithelial staining profile but lack intensity associated with acinic cell carcinoma
 - Pancytokeratins, low-molecular-weight cytokeratins (AE1/AE3, CAM5.2, CK7, CK8, CK19), EMA and CEA positive
 - Amylase positive:
 - Of limited diagnostic utility as only a minority of cases (15%) express amylase
 - Sox10 positive
 - Variable immunoreactivity seen with S100 protein and vimentin:
 - S100 protein may be positive but typically focal or limited in extent.
 - Mammaglobin typically absent but may be focally positive
 - p63, calponin, actins negative
 - GATA-3 (nuclear) staining may be present but when present is focal rather than diffuse:
 - Diffuse GATA-3 staining in salivary gland neoplasm typically limited to salivary duct carcinoma and mammary analogue secretory carcinoma
 - Low labeling indices as seen by Ki67 staining
 - Absence of thyroglobulin and TTF1
- Electron microscopy:
 - Ultrastructural findings are characterized by the presence of numerous round, electron-dense cytoplasmic secretory granules.
 - Rough endoplasmic reticulum and mitochondria are present; junctional complexes and microvilli may be identified.
 - Basal lamina separates tumor cells from stroma.

- Cytogenetics and molecular biology:
 - Absence of *ETV6* translocation
 - No specific findings:
 - Alterations of chromosome 4p, 5q, 6p, and 17p
 - Loss of heterozygosity (LOH) in at least one of the 20 loci on chromosomes 1, 4, 5, 6, and 17

High-Grade Transformation (“Dedifferentiated”) of Acinic Cell Carcinoma

- Composed of histomorphologically “conventional” acinic cell carcinoma with associated high-grade carcinoma
- May occur rarely at initial presentation or in a long-standing or recurrent tumor
- Clinical presentation may include rapidly enlarging lesion, pain, cranial neuropathy (e.g., facial nerve palsy)
- High-grade carcinoma may include undifferentiated/poorly differentiated carcinoma or poorly differentiated adenocarcinoma characterized by presence of sheets of epithelial cells sometimes with cribriform growth lacking evidence of cellular differentiation with marked nuclear pleomorphism, increased nuclear-to-cytoplasmic ratio, increased mitotic figures including atypical mitoses, necrosis, and high proliferation indices.
- Immunohistochemical staining of high-grade component may be characterized by strong membrane staining for CK18 and beta-catenin, and nuclear staining for cyclin-D1.
- Associated with poor prognosis

Differential Diagnosis

- Normal salivary gland parenchyma:
 - Retention of normal lobular architecture of the salivary gland parenchyma as well as the presence of other salivary gland cellular components (e.g., striated ducts, interlobular ducts) assist in differentiating normal gland from acinic cell adenocarcinoma.
- Mammary analogue secretory carcinoma (MASC):
 - Share overlapping histomorphologic features with acinic cell carcinoma but in contrast to acinic cell carcinomas, MASCs:
 - Lack cells with basophilic cytoplasm and zymogen-like secretory granules
 - Show diffuse and strong mammaglobin and S100 protein
 - Have *ETV6* translocation
- Mucoepidermoid carcinoma
- Cystadenocarcinoma
- Salivary and nonsalivary gland neoplasms containing clear cells, including:
 - Oncocytoma
 - Myoepithelioma

- Mucoepidermoid carcinoma
- Epithelial-myoepithelial carcinoma
- Clear cell adenocarcinoma
- Metastatic renal cell carcinoma

- Acinic cell adenocarcinomas with follicular pattern may simulate thyroid follicular epithelial neoplasms.

Treatment and Prognosis

- Complete surgical excision is preferred treatment and may consist of either conservative parotidectomy when the tumor is limited to the superficial lobe or total parotidectomy when the deep lobe of the parotid is involved.
- Radiation therapy is generally not used as a primary mode of treatment but may be used for:
 - Tumors that cannot be completely resected
 - Metastatic disease
- Generally are indolent neoplasms cured by complete surgical removal, however:
 - Approximately 35% recurrence rate
 - Approximately 16% metastatic rate:
 - Depending on primary site of occurrence regional lymph node metastasis may include the pre-auricular lymph nodes (parotid tumor), submandibular and upper jugular chain lymph nodes (submandibular tumor), submental lymph nodes (lip tumor), base of skull (palate tumor), submandibular, post-auricular and level II accessory lymph nodes (intraoral tumors)
 - Distant visceral spread includes lungs, liver, bone, and brain
 - Approximately 16% disease-associated death rate
- Most recurrences and metastases occur within 5 years of initial therapy; however, recurrent tumor and metastatic disease may occur years/decades after initial treatment.
- Survival statistics include:
 - 5-year 91%
 - 10-year 83%
 - 20-year 67%
- Adverse prognostic factors may include:
 - Multiple recurrences and metastasis (regional lymph nodes, distant visceral)
 - Short duration of symptoms
 - Submandibular tumors more aggressive than parotid tumors
 - Patients more than 30 years of age
 - Neoplasms larger than 3 cm
- Clinical staging is better predictor of prognosis than histology with poorer outcome associated with:
 - Large size and infiltrative growth
 - Involvement of the deep lobe of parotid
 - Incomplete resection

- Favorable prognostic factors may include:
 - Occurrence in minor salivary glands
 - Longer duration of symptoms
 - Patients under 30 years of age
 - Presence of dense lymphoid stroma with well-developed germinal centers
- Histologic high-grade transformation associated with poor prognosis:
 - Increase in locoregional (lymph node) and distant visceral metastases:
 - High propensity for nodal metastases indicates need for neck dissection at the time of diagnosis.
 - Increase in mortality rates due to tumor dissemination
 - Median overall survival of 4.3 years reported with range of 1 to 9 years
- Histologic features that may be associated with adverse prognosis include:
 - High proliferation indices (more than 5%)
 - Neurotropism
 - Anaplasia
 - Necrosis
 - Depletion of lymphocytes in stroma

MAMMARY ANALOGUE SECRETORY CARCINOMA (MASC) (Figs. 20-62 through 20-66)

Definition: Distinctive recently described low-grade salivary gland neoplasm with features resembling acinic cell carcinoma and (low-grade) cystadenocarcinoma displaying strong similarities to secretory carcinoma of breast including t(12;15)(p13;q25) translocation resulting in *ETV6-NTRK3* gene fusion.

Synonym: “Zymogen-poor” acinic cell carcinoma: in all likelihood all/most previous designations as zymogen-poor acinic cell carcinomas are in reality MASCs.

Clinical

- Slightly more common in males than females; occurs over a wide age range of 21 to 75 years, with a mean age of 46 years
- Most common in parotid gland but may occur in other major glands as well as in minor salivary glands
- Most common presentation is as a painless mass
- Etiology:
 - No known causes

Pathology

Fine-needle aspiration biopsy:

- Variably cellular smears
- Architectural patterns may include:

- Intact clusters with sheet-like or papillary structures
- Dispersed and dissociated cells
- Cytomorphology consists of bland tumor cells with small to medium-sized round to oval nuclei, with a smooth contour and indistinct or small nucleoli, and vacuolated cytoplasm lacking intracytoplasmic zymogen granules
- Many histiocytes, some of which contained hemosiderin pigments, and variously shaped mucinous material may be evident in background or within the epithelial clusters.
- Absence of matrix tissue or stromal spindled cells

Histology

- Circumscribed but unencapsulated lesion often with lobulated appearance divided by fibrous septa
- Growth patterns may include microcystic, (macro) cystic, tubular, papillary, solid, and follicular (thyroid-like):
 - Multiple growth patterns may be seen in a single case.
- Invasion often present, including infiltration of non-neoplastic salivary gland parenchyma and fibroconnective tissue:
 - Perineural and lymph-vascular invasion may be present.
 - Extraparenchymal extension may be identified.
- Lesional cells are cuboidal to polygonal with round to oval nuclei with vesicular to finely granular chromatin, small distinct centrally located nucleoli surrounded by pale pink granular or vacuolated-appearing cytoplasm:
 - Serous acinar differentiation in form of intracytoplasmic basophilic granules not a feature
- Intraluminal secretions including bluish to eosinophilic material variably present within microcystic and tubular spaces
- Absence of significant nuclear pleomorphism, increased mitotic activity, or necrosis
- Reactive and degenerative changes similar to those seen in acinic cell carcinoma may be present, including:
 - Infarction and necrosis
 - Hemorrhage, recent and remote (i.e., hemosiderin deposition):
 - Intracytoplasmic hemosiderin deposition can be seen within tumor cells
 - Cholesterol granuloma formation
 - Calcifications
- Histochemistry:
 - Intraluminal secretory material positive for mucicarmine, PAS with and without diastase, and alcian blue

Fig. 20-62. Mammary analogue secretory carcinoma.

A, Circumscribed but unencapsulated lesion with lobulated appearance divided by fibrous septa composed of solid tumor nests. Additional growth patterns that may be seen from case to case and even within the same case include **(B)** tubular (secretory); **(C)** microcystic and solid; **(D)** papillary and cystic; **(E)** follicular (thyroid-like). Intraluminal eosinophilic appearing secretions are variably present within microcystic and tubular spaces.

Fig. 20-63. Macrocystic mammary analogue secretory carcinoma.

A-D, Uncommonly, the tumor may have predominant or exclusive macrocystic growth. Limited but identifiable characteristic cellular foci are seen (*arrowhead* in **A** and seen at higher magnification in **B**). Note the single layer of lesional cells lining the cyst are histologically similar to those in the cellular foci.

- Immunohistochemistry:
 - Mammaglobin
 - Diffuse and strong reactivity ranging from 50% to 100% of cells (mean 91%)
 - Present in cytoplasm and intraluminal secretory material
 - Mammaglobin highly sensitive for MASC but may be present in variety of tumors that do not harbor the ETV6 translocation
 - Absent or limited (focal) reactivity in acinic cell carcinoma
 - Should not be indiscriminately used as a confirmatory test for MASC
 - S100 protein
 - Diffuse and strong reactivity
 - Seen in a wide variety of salivary gland lesions/neoplasms
 - In conjunction with diffuse and strong mammaglobin staining as well as appropriate histologic findings, can be used to diagnose MASC even without cytogenetic testing (see below)
 - GATA binding protein 3 (GATA-3):
 - A member of GATA family of zinc finger transcription factors that regulate normal development of various tissue and cell types including breast, T-lymphocytes, kidney, nerve, and skin
 - Initially, immunohistochemical nuclear staining for GATA-3 believed to be restricted mostly to neoplasms of breast and urothelial origin
 - Evidence now shows GATA-3 staining in salivary gland neoplasms but consistent strong and diffuse (nuclear) staining (i.e., >50% of cells) limited to MASC and salivary duct carcinoma

Fig. 20-64. Mammary analogue secretory carcinoma.

A through **D**, Lesional cells are cuboidal to polygonal with round to oval nuclei, vesicular to finely granular chromatin, small distinct to larger nucleoli surrounded by pale pink granular or vacuolated-appearing cytoplasm. Focally intracytoplasmic hemosiderin deposition may be seen within lesional cells (**D**, arrowheads). The overall features are reminiscent of those seen in acinic cell carcinoma, except there is an absence of serous acinar differentiation in the form of intracytoplasmic basophilic granules. Nevertheless, immunohistochemical staining and/or molecular analysis may be required to differentiate mammary analogue secretory carcinoma from acinic cell carcinoma.

among GATA-3 positive salivary gland neoplasms:

- Other GATA-3+ salivary gland tumors include:
 - Acinic cell carcinoma, adenoid cystic carcinoma, epithelial-myoepithelial carcinoma, mucoepidermoid carcinoma, oncocytic carcinoma, oncocytoma, pleomorphic adenoma, Warthin tumor
 - Staining in these other neoplasms tends to be less than diffuse and/or strong.
 - Some of these other neoplasms may include diffuse and/or strong reactivity but

histologically would not be confused with MASC, including oncocytoma and Warthin tumor

- Cytokeratins:
 - Diffuse and strong staining for AE1/AE3, CAM5.2, CK7, CK8, CK18, CK19
- Other markers:
 - Diffuse and strong vimentin, EMA and STAT5a (signal transducer and activator of transcription 5a) staining
 - Significant reactivity for gross cystic disease fluid protein 15 (GCDFP-15) especially intraluminal secretory material

Fig. 20-65. Mammary analogue secretory carcinoma.

Intraluminal secretory material is positive for (A) mucicarmine and (B) periodic acid Schiff with diastase.

Fig. 20-66. Mammary analogue secretory carcinoma.

Immunohistochemical staining includes diffuse reactivity for (A) mammaglobin, (B) S100 protein, and (C) GATA3 (nuclear).

- Basal cell/myoepithelial cell markers:
 - p63, calponin, CK14, smooth muscle actin, and CK5/6 are essentially negative
 - Isolated nuclear p63 positive may be identified.
- Discovered on GIST1 (DOG-1):
 - Typically negative
- Cytogenetics and molecular genetics:
 - t(12;15)(p13;q25) chromosomal translocation resulting in *ETV6-NTRK3* gene fusion
 - To date, restricted to MASCs
 - May be identified by FISH or RT-PCR

High-Grade Transformation (“Dedifferentiated”) of MASC

- Rare and recently reported occurrence in three cases located in parotid gland
- Characterized by accelerated clinical course in a long-standing lesion (23 years), relatively recent identified lesion (2 years), or recurrent neoplasm
- Histologically, composed of two distinct sharply delineated carcinomatous components including:
 - Conventional MASC (see previous)
 - High-grade transformation characterized by anaplastic cells arranged in trabecular pattern with marked nuclear pleomorphism and absence of intraluminal secretory material
 - Perineural invasion, necrosis (comedotype), and desmoplastic stroma consistently identified
 - Extraglandular invasion including into skin consistently identified
- Immunohistochemical staining included:
 - Ki67 (MIB1)
 - For low-grade component median proliferation index was 23% (range 15 to 35)
 - For high-grade component, significant increase in proliferative activity with Ki67 index between 45% and 70% (median 53%)
 - Strong membranous staining for *EGFR* particularly in high-grade component
 - Median cyclin-D1 index higher in high-grade component (50%; range 40% to 60%) as compared with low-grade component (8.3%; range 5% to 15%)
 - p53 protein absent in low-grade component in two of three cases, but increased p53 immunoreactivity in high-grade component in all three cases
 - High-grade component revealed strong membrane staining for *EGFR* and β -catenin, cytoplasmic/nuclear staining for S100 protein
 - Cytokeratins (AE1/AE3, CK7, CK8, CK18, CK19), vimentin, S100 protein and mammaglobin stained both components with equally strong and diffuse intensity

- Cells of both components showed focal staining with EMA, GCDFP-15, and STAT5a
- Staining with calponin, CK14, CK5/6, CK20, p63 protein, androgen receptor, and *HER-2/neu* negative in both components
- Analysis for presence of the *ETV6-NTRK3* fusion transcript revealed positivity in both high-grade and “conventional” or low-grade component of MASC in two of three cases reported:
 - One case was negative in both its elements for the t(12;15) translocation, but *ETV6* gene rearrangement was detected in both components in all three cases.
- Analysis of *TP53* and *CTNNB1* gene mutations in the HG component of MASCs as well as detection of copy number aberration of *EGFR* and *CCND1* gene did not harbor any abnormalities.
- All three patients died of disseminated disease within 2 to 6 years after diagnosis:
 - Locoregional (nodal) metastasis, with or without extranodal extension
 - Distant metastasis

Differential Diagnosis

- Acinic cell carcinoma:
 - Presence of cells with basophilic granular cytoplasm
 - Presence of DOG1 immunoreactivity
 - Absence of diffuse and strong mammaglobin, S100 protein, and GATA-3 staining
 - Absence of *ETV6-NTRK3* gene fusion
- Low-grade cribriform cystadenocarcinoma
- Mucoepidermoid carcinoma, low grade

Treatment and Prognosis

- Complete surgical resection is preferred treatment.
- Efficacy of radiotherapy (preoperative or postoperative) uncertain
- In a limited number of studies with long-term follow-up to date, overall indolent clinical course reported:
 - Mean disease-free survival of 92 months
 - Majority of cases reported without evidence of disease from 27 months to 10 years
 - Minority of cases with recurrent and/or metastatic disease

ADENOCARCINOMA, NOT OTHERWISE SPECIFIED (NOS) (Figs. 20-67 through 20-71)

Definition: Malignant epithelial salivary gland neoplasm with glandular or ductal differentiation but without other specific histologic features allowing for a more definitive classification.

Fig. 20-67. Adenocarcinoma, NOS.

Parotid gland adenocarcinoma, NOS, high-grade, fine-needle aspiration biopsy. Cell clusters showing high-grade cytologic features and formation of gland- or duct-like structures.

Clinical

- Shrinking category of salivary gland neoplasms given identification of more specific tumor types but still considered among more common malignant salivary gland neoplasms
- More common in women than in men; occurs over a wide age range but is most frequently seen in the fifth to eighth decades of life; rarely occurs in children and adolescents
- Occurs in major and minor salivary glands:
 - In major glands, most common site of occurrence is parotid gland, representing single most common site of occurrence; may also occur in submandibular and rarely in the sublingual glands
 - Among minor salivary gland sites, most commonly occur in intraoral sites particularly palate followed by buccal mucosa, tongue, and lips (upper greater than lower)

Fig. 20-68. Parotid gland adenocarcinoma, low-grade, NOS.

A, At low magnification the tumor is infiltrative with solid and cribriform growth. **B**, At higher magnification there is back-to-back glandular (cribriform) growth composed of a uniform single cell type characterized by cuboidal to round vesicular nuclei, minimal nuclear pleomorphism, and absence of increased mitotic activity. There are no features diagnostic for a more specific salivary gland tumor, hence the designation "not otherwise specified (NOS)."

- Symptoms relate to site of occurrence:
 - In major glands symptoms vary and may include:
 - Solitary, asymptomatic mass
 - Pain, cranial nerve paralysis occurs in minority of patients (approximately 20%)
 - Pain more common in submandibular gland tumors
 - Cutaneous involvement (fixation) may occur.
 - In minor glands:
 - Asymptomatic submucosal mass with ulceration and/or osseous involvement in a minority of cases
 - Duration of symptoms varies from months to years.
- Etiology:
 - No known causes

Fig. 20-69. Parotid gland adenocarcinoma, intermediate-grade, NOS.

A, Parotid tumor with invasion into the adjacent salivary gland parenchyma (*right*) showing trabecular and glandular growth. **B,** At higher magnification the glands are composed of cells with greater nuclear pleomorphism and more solid growth as compared with low-grade tumors but lacking the marked nuclear pleomorphism, increased mitotic activity, atypical mitoses, and necrosis seen in higher-grade tumors.

Pathology

Gross

- Varies from delineated and/or circumscribed to poorly demarcated and infiltrative
- Firm to hard, tan-white mass measuring from 2 to 10 cm in diameter
- Hemorrhage, necrosis, and cystic change may be seen.

Histology

- Display histologic heterogeneity but common to all growth patterns and cytologic appearances is the presence of an infiltrative neoplasm showing evidence of glandular or ductular features and an

Fig. 20-70. Parotid gland adenocarcinoma, high-grade, NOS.

Large parotid mass that was clinically painful involving the facial nerve causing facial nerve paralysis and facial distortion/asymmetry.

absence of epidermoid differentiation or other differentiation that may be indicative of another tumor type:

- Polymorphous growth patterns, including glandular or ductular structures, as well as solid, sheetlike, tubular, cribriform, lobular, cell nests, islands, and cord-like growth:
 - Multiple growth patterns seen from case to case and even within same case
- Cystic and papillary growth may be focally present but is limited in extent as more extensive cystic and papillary growth likely would be indicative of another tumor (e.g., cystadenocarcinoma).
- In higher grade neoplasms, glandular features may require diligent searching or may be represented by primitive attempts at gland or duct formation.
- Cytomorphologic diversification also seen ranging from cells having uniform appearance and distinct cell borders to cells with marked nuclear pleomorphism and indistinct cell borders.

Fig. 20-71. Parotid gland adenocarcinoma, high-grade, NOS.

A, Parotid tumor that is unencapsulated and infiltrative into parotid gland parenchyma; there was also extensive extraglandular invasion with infiltrative growth into subcutaneous tissue and dermis (not shown); **(B)** complex glandular growth; **(C)** at higher magnification residual gland formation is present (*arrowheads*) with neoplastic cells characterized by enlarged and pleomorphic nuclei, prominent nucleoli, mitotic figures, and necrosis; **(D)** peri- and intraneural invasion.

- Cell types that can be seen include:
 - Cells with clear cytoplasm
 - Cells with oncocytic cytoplasm
 - Plasmacytoid-appearing cells
 - Sebaceous cells
 - Absence of mucocytes and epidermoid cells
- Histologic grading into low, intermediate, and high is based on degree of gland formation (differentiation), cellular pleomorphism, and mitotic activity:
 - Low grade:
 - Well circumscribed but at least focally invasive
 - Numerous gland or duct-like structures
 - Relatively uniform cytomorphologic features composed of a single cell type characterized by cuboidal to round tumor cells with small nucleoli, abundant cytoplasm, distinct cell borders, and little nuclear pleomorphism with few mitotic figures
 - Intermediate grade:
 - Glands or duct-like structures are readily seen.
 - In comparison to low-grade tumors there are greater cellular pleomorphism and more mitoses but usually atypical mitoses are not identified.
 - High grade:
 - Generally grow in solid sheets
 - Cells marked by anaplastic cytologic features, including enlarged, hyperchromatic and pleomorphic nuclei, small to prominent nucleoli, numerous mitoses, including atypical forms, necrosis, and hemorrhage

- Presence of glandular differentiation may require extensive searching or the use of special stains (e.g., mucicarmine).
- Stroma may be collagenized and occasionally may appear myxoid or mucinous.
- Extensive infiltrative growth generally seen in higher grade lesions and may include neurotropism, lymph-vascular invasion, invasion into fibroconnective tissue, and extraparenchymal invasion into soft tissues
- Some tumors may contain areas with focal features of other tumor types (e.g., adenoid cystic carcinoma, acinic cell adenocarcinoma, epithelial-myoepithelial tumor); however, these foci are very limited and do not justify exclusion from classification as adenocarcinoma, NOS.
- Histochemistry:
 - Intraluminal mucicarmine and diastase-resistant, PAS-positive material
 - Intracytoplasmic mucin generally not identified
 - Diastase-sensitive, PAS-positive intracytoplasmic material indicative of glycogen may be present.
- Immunohistochemistry:
 - Epithelial markers positive including cytokeratins (e.g., AE1/AE3, CAM5.2, CK7), CEA, and EMA
 - Myoepithelial-related markers generally negative including p63, calponin
 - May be positive for mammaglobin and GCDFP-15
- Metastatic tumor more common in histologically higher-grade tumor and in patients previously treated
- Most accurate factor in predicting survival is clinical stage:
 - 15-year survival rates include:
 - 54% for stage I
 - 31% for stage II
 - 3% for stage III
 - Histologically higher grade tumors tend to be clinically stage III tumors.
 - Histologically lower grade tumors tend to be clinically stage I tumors.
 - Other factors correlating with prognosis include:
 - Histologic grade:
 - Lower histologic grade lower rate of local recurrence(s) or metastatic (regional or distant) disease and the longer disease-free survival
 - Higher histologic grade the higher the rate of local recurrence(s) or metastatic (regional or distant) disease and the shorter the disease-free survival
 - Site of involvement:
 - Intraoral tumors more favorable prognosis than parotid gland and submandibular gland tumors
 - ◻ A higher percentage of submandibular gland adenocarcinomas are high-grade neoplasms as compared with parotid-based neoplasms accounting for greater likelihood of submandibular adenocarcinomas metastasizing to regional lymph nodes than lesions of parotid gland or intraoral minor salivary glands.

Differential Diagnosis

- Pleomorphic adenoma
- Monomorphic adenomas
- Epithelial-myoepithelial carcinoma
- Adenoid cystic carcinoma
- Polymorphous low-grade adenocarcinoma
- Cystadenocarcinomas
- High-grade mucoepidermoid carcinoma
- Metastatic adenocarcinoma

Treatment and Prognosis

- Complete surgical excision is preferred treatment:
 - Extent of the surgery dependent on location and clinical stage of disease (subtotal versus total glandectomy)
- Neck dissection dependent on presence of overt neck disease or clinical suspicion of nodal involvement
- Postoperative adjuvant radiotherapy used in advanced clinical stage neoplasms
- Local recurrence not uncommon, especially in high-grade neoplasms
- Metastatic disease occurs in approximately 26% of patients with cervical lymph nodes and lungs most commonly affected sites:
 - Other metastatic sites may include bone, skin, and abdominal sites.

ADENOID CYSTIC CARCINOMA

(Figs. 20-72 through 20-81)

Definition: Malignant epithelial salivary gland neoplasm predominantly composed of modified myoepithelial or basal (abluminal) cells with a minor component composed of ductal (luminal) structures characterized by its histologic appearance, tendency to invade nerves, and protracted but nonetheless relentless clinical course.

Synonyms: Cyndroma (old term used for cribriform type)

Clinical

- Represent approximately 10% to 12% of all malignant salivary gland neoplasms
- Slightly more common in women than in men; occurs over wide age range but most commonly occurs in the fifth through seventh decades of life:

Fig. 20-72. Adenoid cystic carcinoma.

Adenoid cystic carcinoma may originate anywhere in the upper aerodigestive tract, including (A) parotid gland; (B) submandibular gland; (C) hard palate; (D) soft palate; and (E) lip.

Fig. 20-73. Adenoid cystic carcinoma, resection specimens.

A, Submandibular gland replaced by a solid neoplasm replacing most of the gland; the tumor in part appears circumscribed but has infiltrative borders. **B**, Maxillary sinus neoplasm that invaded through the palate with involvement of the oral cavity.

- Generally uncommonly encountered prior to the third decade of life
- In major salivary glands, primarily involves parotid and submandibular glands:
- Nearly half arise in minor salivary glands:
 - May involve minor salivary glands throughout upper respiratory tract but most commonly involves intraoral sites:
 - Palate most common intraoral site
 - Second only to parotid gland as most common site of occurrence
 - Other minor salivary gland sites of involvement include:
 - Tongue, sinonasal tract, ceruminous glands of external auditory canal, and lacrimal gland:
 - More common tumor type of lacrimal glands
- Symptoms vary according to site involved but most common complaint is a slow-growing mass with or

Fig. 20-74. Adenoid cystic carcinoma, fine-needle aspiration biopsy.

The aspirate is characterized by the presence of spheres, globules, and elongated cylinders of acellular stroma surrounded by uniform-appearing basaloid cells.

without associated pain or cranial nerve (e.g., facial nerve) paralysis:

- Other symptoms include:
 - Airway obstruction, epistaxis, otalgia, and hoarseness
 - Rarely, may present as a rapidly enlarging mass
 - Ulceration is often present in mucosal-based tumors.
 - Fixation to surrounding tissues is often present.
- Etiology:
 - No known cause

Pathology

Gross

- Circumscribed, unencapsulated, partly encapsulated, poorly circumscribed to infiltrative, solid, rubbery to firm, tan-white to gray-pink mass measuring from 2 to 4 cm in greatest dimension

Fine-Needle Aspiration Biopsy

- Aspirates are characterized by presence of relatively uniform cells associated with (surrounded by or

Fig. 20-75. Adenoid cystic carcinoma.

A, Infiltrating neoplasm with multiple (polymorphous) growth patterns including cribriform, solid, tubular/ductular and trabecular. **B**, “Classic” cribriform growth is present (lower portion of the illustration) with prominent intracystic and extracellular hyalinized eosinophilic (reduplicated basement membrane-like) material.

Fig. 20-76. Adenoid cystic carcinoma.

A, Cribriform pattern creating a “Swiss cheese” configuration includes pseudocysts lined by abluminal (modified myoepithelial) cells containing basophilic mucinous material. **B**, Tubular growth pattern with intraluminal eosinophilic to basophilic-appearing material. **C**, Cystic spaces filled with eosinophilic hyaline (basement membrane-like) material. **D**, Extracellular eosinophilic hyaline (basement membrane-like) material resulting in trabecular and cord-like growth.

Fig. 20-77. Adenoid cystic carcinoma.

A and **B**, The abluminal (modified myoepithelial) cells dominate in any given tumor but true luminal (epithelial) cells can be seen forming glandular spaces (arrows in **A**; arrowheads in **B**) but may be limited in extent and difficult to identify.

clinging to) spheres, globules, and elongated cylinders of acellular stroma:

- Diagnosis often can be made by FNAB.
- Matrix globules appear metachromatic by Romanowsky staining, purple to pink by Giemsa staining, and pale green or light orange by Papanicolaou staining.
- Similar to pleomorphic adenoma, the diagnosis is based on the presence of characteristic extracellular matrix material.
- Matrix of pleomorphic adenomas tends to be fibrillar and less well defined as compared to the extracellular matrix material associated with adenoid cystic carcinoma. However, overlapping features between the extracellular matrix material of adenoid cystic carcinoma, pleomorphic adenoma, basal cell adenoma, acinic cell adenocarcinoma, and other tumors may create difficulties in the cytologic diagnosis.

Fig. 20-78. Adenoid cystic carcinoma, solid variant.

A, Tumor cells arranged in solid nests and present in at least 30% of a given tumor. **B**, The cellular component in the solid variant tends to include larger more pleomorphic nuclei with increased mitotic activity.

Fig. 20-79. Adenoid cystic carcinoma.

A, Characteristically perineural invasion (neurotropism) is identified. **B**, Less frequently invasion into soft tissues, including skeletal muscle, may be identified.

Fig. 20-80. Adenoid cystic carcinoma.

Immunohistochemical staining is not typically required in diagnosing adenoid cystic carcinoma but among the markers and staining patterns seen include (A) p63 dedicated to the abluminal (myoepithelial) cells but not luminal lining cells; (B) CD117 dedicated to luminal lining cells but not abluminal (myoepithelial) cells. NOTE: CD117 is not uniquely identified in adenoid cystic carcinoma but can be seen in other salivary gland neoplasms, including benign and malignant neoplasms.

- Cells of adenoid cystic carcinoma are small with uniform, hyperchromatic nuclei, limited cytoplasm, high nuclear-to-cytoplasmic ratio, and indistinct cell borders.
- Cells may be arranged individually or in loose syncytial fragments.
- In solid variant of adenoid cystic carcinoma:
 - Cells may be larger with greater variability in the size and shape of the nuclei.
 - Nucleoli may be identifiable.
 - There is often loss of cellular cohesion with overlapping of cells.
 - Necrosis and mitoses may be seen.

Fig. 20-81. Adenoid cystic carcinoma vs PLGA.

The differentiation between adenoid cystic carcinoma and polymorphous low-grade adenocarcinoma (PLGA) can be extremely challenging. Although there is suggestion that staining patterns of p63 and p40 may contrast between these two lesions, thereby allowing for differentiation, such findings are not consistently identified. Differentiation may be predicated on the cytomorphologic findings. *Left*, In adenoid cystic carcinoma the lesional cells are composed of smaller isomorphic hyperchromatic nuclei lacking significant pleomorphism and mitotic activity; *right*, in PLGA the lesional cells are comprised of larger isomorphic vesicular nuclei lacking significant pleomorphism and mitotic activity.

- MYB immunohistochemical staining in FNAB specimens potentially useful in diagnosis of adenoid cystic carcinoma (positive nuclear staining) and in differential diagnosis from pleomorphic adenoma (negative staining)
 - Reported sensitivity of MYB on FNAB of 80% and specificity of 100% relative to pleomorphic adenoma

Histology

- Typically unencapsulated and infiltrative with varied growth patterns (i.e., polymorphic) including cribriform, tubular/ductular, and solid:
 - Individual neoplasms may have single growth but characteristically are composed of multiple patterns of which any one may predominate.
 - Some cases may be encapsulated without invasive growth with diagnosis predicated on characteristic light microscopic features.
 - Common to all histologic patterns (see below) is proclivity to peri- and, less often, intraneural invasion:
 - Not pathognomonic for adenoid cystic carcinoma

- Seen in a variety of other salivary gland and non-salivary gland tumors
- In adenoid cystic carcinoma tendency for infiltration along nerves beyond main tumor
- In addition to neurotropism, invasion into adjacent structures including salivary gland parenchyma, fibroconnective tissues (e.g., fat, skeletal muscle) and lymph-vascular or angioinvasion
- Generally tend to be resistant to presence of squamous differentiation:
 - Identification of squamous component (cells with intercellular bridges, keratinization, squamous eddies) supports an alternative diagnosis rather than adenoid cystic carcinoma
- Cellular components:
 - Basaloid-appearing (abluminal) cells:
 - Represent modified myoepithelial or basal cells
 - Dominant cell type
 - Surround pseudocysts
 - Composed of uniform angular to oval, hyperchromatic nuclei with absent nucleoli and scanty cytoplasm with indistinct cell borders:
 - Occasional cells with small nucleoli may be seen
 - Eosinophilic to clear-appearing cytoplasm may be present
 - Nuclear pleomorphism and mitotic activity are typically not present.
 - Low or 1:1 nuclear-to-cytoplasmic ratio.
 - Ductal (luminal) structures:
 - True glandular spaces
 - Scattered among basaloid cells and may be difficult to identify
 - Characterized by presence of cells with round nuclei and eosinophilic-appearing cytoplasm
- Interstitial stroma, from which the epithelial component is sharply demarcated, varies in appearance from myxoid to mucinous to hyalinized

Cribriform Pattern

- Most characteristic (“classic”) pattern
- Arrangement of cells in “Swiss cheese” or sieve-like configuration with many oval or circular microcystic (pseudocystic) spaces
- Microcysts are pseudocysts (not true epithelial lined glandular lumens) contiguous with stromal connective tissue and contain basophilic mucinous substance and/or hyalinized eosinophilic material:
 - Cystic spaces are pseudocysts, which are extracellular and lined by replicated basement membrane.
 - Basophilic mucinous substance is alcian blue positive.
 - Hyalinized eosinophilic material is PAS positive.

Tubular Pattern

- Often seen in association with cribriform pattern
- Cells are arranged in ducts or tubules.
- Dual cell differentiation (i.e., ductal and myoepithelial cells) present with readily identifiable epithelial-lined true ducts surrounded by myoepithelial (abluminal) cells.
- Ducts or tubules may be empty or contain faintly eosinophilic mucinous material.

Solid Pattern

- Least common pattern
- Neoplastic cells arranged in sheets or nests of varying size and shape
- Little tendency to form cystic spaces, tubules, or ducts
- Cytomorphology similar to cribriform and tubular patterns but findings in solid pattern may include:
 - Tendency for cells to be larger with larger nuclei
 - Greater nuclear pleomorphism
 - Increased mitotic activity (5 or more mitoses per 10 high-power fields)
 - Necrosis (confluent foci and individual cell)
- Histologic grading:
 - Grade I:
 - Mostly tubular with some cribriform patterns
 - Absence of solid pattern
 - Absence of nuclear pleomorphism and increased mitotic activity
 - Grade II:
 - Pure cribriform pattern or mixed tubular/cribriform; solid patterns may be present but not >30%
 - Slightly greater degree of nuclear pleomorphism and mitotic activity than Grade I
 - Grade III:
 - >30% solid pattern
 - More significant nuclear pleomorphism and increased mitotic activity over Grade II:
 - Larger cells with larger nuclei
 - 5 or more mitoses per 10 high-power fields
 - Necrosis often present:
 - Confluent foci and individual cell
- Histochemistry:
 - Pseudocysts contain diastase-resistant, PAS-positive, and mucicarmine-positive material.
- Immunohistochemistry:
 - Myoepithelial or basal (abluminal) cells:
 - Cytokeratins, p63, p40, S100 protein, calponin, smooth muscle actin, smooth muscle myosin heavy chain, and vimentin positive
 - Cytokeratin tends to be less intensely reactive as compared to ductal cells
 - Glial fibrillary acidic protein may be focally positive.

- Ductal (luminal) cells:
 - Cytokeratins (pancytokeratin, CK7, CK14, CK17, CK19), S100 protein, epithelial membrane antigen (EMA) and carcinoembryonic antigen (CEA) and c-kit (CD117) positive:
 - Cytokeratin tends to be more intensely reactive as compared to myoepithelial or basal cells.
- IHC findings including pairing p63 and p40 reported to assist in differentiating pleomorphic adenoma (PA) from polymorphous low-grade adenocarcinoma (PLGA) and adenoid cystic carcinoma (AdCC) include:
 - PA: p63+/p40+
 - Cellular PA: concordant p63+/p40+ or p63–/p40–
 - PLGA: consistent p63+/p40–
 - AdCC: p63+/p40+

CAUTIONARY NOTE: While p63/p40 IHC panel can be a valuable tool for making distinction between PA, PLGA, and AdCC it is not infallible and any given example may demonstrate divergence from the reported p63/p40 immunophenotype.
- Additional immunohistochemical findings may include:
 - Expression of MYB protein (see below under Cytogenetics):
 - Identified in translocation-positive and translocation-negative adenoid cystic carcinomas
 - More than 80% of adenoid cystic carcinomas reported to stain positive for MYB protein
 - 14% of nonadenoid cystic carcinoma neoplasms also reported to express MYB protein
 - MYB immunostaining may be useful for diagnosis of adenoid cystic carcinoma, but neoplasms in differential diagnosis may also express MYB protein.
 - Ki67 (MIB1) staining:
 - Proliferative indices reported to be significantly higher in adenoid cystic carcinoma (21%) as compared with polymorphous low-grade adenocarcinoma (2%)
 - Increased proliferation index may not be present in all cases of adenoid cystic carcinoma and by itself does not unequivocally differentiate it from polymorphous low-grade adenocarcinoma.
 - Reactivity for mammaglobin may be present, including cases with positive staining and cases with negative staining.
 - May be DOG-1 positive, showing distinctive combined apical ductal and membranous/cytoplasmic myoepithelial staining profile

- GATA-3 staining may be present but not diffusely as seen in salivary duct carcinoma and mammary analogue secretory carcinoma.
- Sox10 variably positive in abluminal and luminal cells
- No immunoreactivity for neuroendocrine markers (e.g., synaptophysin, chromogranin), GDCP15, and PLAG1
- Ultrastructure:
 - Ductal (luminal) cells:
 - Microvilli, desmosomes, tonofilaments, and rough endoplasmic reticulum
 - Myoepithelial (abluminal) cells:
 - Variable findings including cytoplasmic processes, cytoplasmic filaments, dense bodies, desmosomes, tonofilaments
 - Pseudocysts contain reduplicated basal lamina.
 - Basal lamina surround epithelial islands.
- Cytogenetic and molecular genetics:
 - Specific chromosomal translocation t(6;9)(q22-23;p23-24) involving the v-myb avian myeloblastosis viral oncogene homolog (MYB) and nuclear factor I/B (NFIB) genes results in *MYB-NFIB* gene fusion identified in adenoid cystic carcinomas:
 - Identified in adenoid cystic carcinomas irrespective of site of occurrence, including salivary glands, sinonasal tract, larynx, tracheobronchial tree, lacrimal gland, as well as non-head and neck sites (e.g., breast, vulva)
 - Gene fusion found in 30% to 50% of cases with increase to 86% when performed on frozen specimen
 - *MYB-NFIB* gene fusion in dermal cylindromas strengthening evidence for common molecular pathways for development of benign and malignant salivary, adnexal, and breast tumors
 - Not detected in other salivary gland neoplasms:
 - 1 purported case of polymorphous low-grade adenocarcinoma reported to express adenoid cystic carcinoma-associated *MYB-NFIB* by RT-PCR analysis
 - Molecular consequences of this alteration incompletely understood but suggest important role in development of adenoid cystic carcinoma
 - Dysregulated microRNAs (miRNA) found in adenoid cystic carcinomas:
 - No significant differences in miRNA expression between *MYB-NFIB* fusion-positive and fusion-negative cases
 - Of highly dysregulated miRNA in adenoid cystic carcinoma, overexpression of miR-17

and miR-20a was significantly associated with poor outcome.

- Upregulation of miR-17-92 may play a role in biology of ACC and could potentially be targeted in future therapeutic studies.
- Additional mutations identified in adenoid cystic carcinoma include:
 - PIK3CA, ATM, CDKN2A, SF3B1, SUFU, TSC1, and CYLD
 - Mutations in SPEN (split ends, homolog of *Drosophila*), which encodes an RNA-binding coregulatory protein, suggest that other changes in transcriptional regulation may involve NOTCH, FGFR, or other signaling pathways in which SPEN participates.
 - Mutations in genes encoding chromatin-state regulators, such as SMARCA2, CREBBP, and KDM6A, reported suggesting aberrant epigenetic regulation in adenoid cystic carcinoma oncogenesis.
 - Mutations in genes central to DNA damage response and protein kinase A signaling also implicated
 - Recurrent mutations in FGF-IGF-PI3K pathway (30% of tumors)
 - Might represent new avenues for therapy

Hybrid Tumors

- Rare occurrence of neoplasm composed of two or more histologic distinct types, each of which conforms with an exactly defined tumor category having an identical origin within same topographic area
 - In contrast, biphasically differentiated tumors are a mixture of two cellular patterns corresponding to a specific classification (e.g., epithelial-myoepithelial carcinoma, adenoid cystic carcinoma, adenosquamous carcinoma, others)
- Most common tumor types include:
 - Adenoid cystic carcinoma
 - Salivary duct carcinoma
 - Epithelial-myoepithelial carcinoma
- Other tumor types that may be seen in hybrid tumors include:
 - Basal cell adenoma
 - Warthin tumor
 - Canalicular adenoma
 - Acinic cell carcinoma
 - Basal cell adenocarcinoma
 - Myoepithelial carcinoma
- Combinations may include multiple malignant tumor types, multiple benign tumor types, and admixture of benign and malignant tumor types.
- May occur in initial clinical presentation or in recurrent tumor
- Prognosis predicated on highest histologic grade malignancy (e.g., salivary duct carcinoma)

High-Grade Transformation (“Dedifferentiation”) in Adenoid Cystic Carcinoma

- Unusual occurrence of a histologically low-grade adenoid cystic carcinoma transforming to a high-grade carcinoma and/or progression from solid adenoid cystic carcinoma to a high-grade carcinoma:
 - Male predominance
 - Age range of fourth to eighth decades with median age in seventh decade (61 years)
 - Occurs most often in association with sinonasal and submandibular adenoid cystic carcinomas
 - Most common morphologies for high-grade component include poorly differentiated cribriform adenocarcinoma and solid undifferentiated carcinoma
 - Micropapillary and squamoid patterns occasionally identified
 - Histologically high-grade transformation distinguished from conventional adenoid cystic carcinoma by presence of:
 - Nuclear pleomorphism with enlargement and irregularity
 - Higher mitotic counts
 - Loss of the biphasic ductal-myoepithelial differentiation
 - Prominent comedonecrosis
 - Fibrocellular desmoplasia
 - Ki-67 and p53 labeling indices elevated in high-grade components
 - Loss or diminished p63 and calponin staining in high-grade components
 - Behavior follows that of less differentiated component and often characterized by:
 - Aggressive growth
 - Nodal metastases
 - Distant metastases
 - Poor prognosis with increased mortality:
 - Death often occurring within 5 years of diagnosis with median overall survival of 12 months

Differential Diagnosis (Table 20-8)

- Pleomorphic adenoma
- Basal cell adenoma:
 - May show cribriform growth
 - Absence of infiltrative growth:
 - Occasional cases of adenoid cystic carcinoma may not be invasive.
 - Cell types, including cells with larger more vesicular nuclei with identifiable nucleoli combined with basaloid hyperchromatic nuclei and squamous differentiation, should allow distinction from adenoid cystic carcinoma.

TABLE 20-8 Adenoid Cystic Carcinoma: Differential Diagnosis

Tumor	Growth Characteristics	Histology	Squamous Differentiation	Neurotropism	Cytogenetics
AdCC, cribriform/tubular	Invasive, polymorphous including “Swiss cheese,” microcysts, tubules, and ductules; reduplicated basement membrane material present	Predominantly composed of uniform basaloid cells surrounding pseudocysts with angular to oval, hyperchromatic nuclei (myoepithelial cells) with admixed epithelial cells lining glandular spaces with round nuclei and eosinophil-appearing cytoplasm (ductal cells); nuclear palisading typically absent	Absent	Yes, as well as invasive into other structures	MYB-NFIB
AdCC, solid	Invasive; sheets and nests of varying size and shape with little tendency to form cystic spaces, tubules or ducts; reduplicated basement membrane material uncommon	Similar to cribriform tubular but cells are larger with larger nuclei, greater nuclear pleomorphism, increased mitotic activity (5 or more mitoses per 10 high-power fields) and necrosis (confluent foci and individual cell); nuclear palisading typically absent	Absent	Yes, as well as invasive into other structures	MYB-NFIB
PLGA	Invasive, polymorphous with cribriform, tubular, solid, single cell, papillary, microcystic; reduplicated basement membrane material present	Isomorphic single-cell type with vesicular nuclei, minimal pleomorphism and absent mitotic activity; nuclear palisading typically absent	May be present typically as metaplastic foci following FNAB or biopsy	Yes, as well as invasive into other structures	None known, although PRKD2 rearrangement reported in a single case
CPA	Encapsulated, may be polymorphous; reduplicated basement membrane material present	Irrespective of cell type (ductal or myoepithelial) or degree of cellularity there usually is an absence of significant pleomorphism, mitotic activity, and no necrosis; nuclear palisading typically absent	May be present typically as metaplastic foci following FNAB or biopsy	No	PLAG1 HMGA2
BCA	Encapsulated, reduplicated basement membrane material present	Combination of basaloid cells, cells with larger more vesicular nuclei; peripheral nuclear palisading may be present	Present but usually limited in extent including squamous eddies	No	None known
BCACA	Invasive reduplicated basement membrane material present	Basaloid cells with variable nuclear pleomorphism and increased mitotic activity; peripheral nuclear may be present	Present but usually limited in extent including squamous eddies	Yes, as well as invasive into other structures	None known

TABLE 20-8 Adenoid Cystic Carcinoma: Differential Diagnosis—cont'd

Tumor	Growth Characteristics	Histology	Squamous Differentiation	Neurotropism	Cytogenetics
BSCC	Invasive, lobular, solid, nested, trabecular, organoid, cribriform; reduplicated basement membrane material may be present	Predominantly basaloid cells with marked pleomorphism, high mitotic rate and necrosis; nuclear palisading typically absent	Present but usually limited in extent and may include intraepithelial dysplasia and/or abrupt keratinization and/or differentiated invasive squamous with keratinization and intercellular bridges	Yes, as well as invasive into other structures	None known
EMC	Invasive, tubular/ductular; typically lacks reduplicated basement membrane material present	Biphasic cell pattern including inner epithelial cells and outer myoepithelial cells	Absent to rare	Yes, as well as invasive into other structures	Limited cases have <i>HRAS</i> exon 3 codon 61 mutation

ACC, Adenoid cystic carcinoma; BCA, basal cell adenoma; BCACA, basal cell adenocarcinoma; BSCC, basaloid squamous cell carcinoma; CPA, cellular pleomorphic adenoma; EMC, epithelial-myoepithelial carcinoma; PLGA, polymorphous low-grade adenocarcinoma.

- Presence of squamous differentiation represents feature not typically associated with adenoid cystic carcinoma
- Absence of *MYB-NFIB* gene fusion
- Polymorphous low-grade adenocarcinoma
 - Overlapping features with adenoid cystic carcinoma
 - Purported differential staining of p63 and p40 than that seen in adenoid cystic carcinoma:
 - Consistent p63+/p40– as compared with adenoid cystic carcinoma showing consistent p63+/p40+
- Basal cell adenocarcinoma
- Basaloid squamous cell carcinoma
- Epithelial-myoepithelial carcinoma
- Recurrence rates range from 16% to 85% and high recurrence rates directly relate to inadequate surgical excision.
- Regional lymph node metastases are uncommon, ranging from 5% to 25%:
 - Neck dissection at time of surgical removal of primary tumor is generally not warranted.
 - Usually occur in association with tumors of submandibular gland origin
- Distant metastasis ranges from 25% to 55%:
 - Generally occur late in disease course following multiple local recurrences
 - Occurs primarily to lungs, bone, brain, and liver
 - Although prolonged survival may occur after metastases, death usually follows within 1 year of identification of metastatic foci.
- Short-term prognosis generally good corresponding to the slow growth leading to prolonged survivals; long-term prognosis is poor
 - 5-year overall survival ranges from 60% to 90%
 - 10-year overall ranges from 29% to 80%
 - 15-year overall survival ranges from 29% to 55%
- Factors affecting prognosis include:
 - Location of primary tumor:
 - Submandibular gland tumors have worse prognosis than parotid gland tumors.
 - Overall, major salivary gland adenoid cystic carcinomas have a better prognosis than their minor salivary gland counterparts, although palatal tumors have a better prognosis.
 - Sinonasal tract tumors have a poor prognosis.
 - Size of the primary tumor:
 - Smaller primary neoplasms that are more amenable to complete resection the better the prognosis

Treatment and Prognosis

- Wide local surgical excision is preferred treatment:
 - Problems confronting surgical removal relate to infiltrative nature with tendency to extend along nerve segments further compounded by their deceptively circumscribed macroscopic appearance
- Radiosensitive and radiotherapy particularly useful (although not curative) in:
 - Controlling microscopic disease after initial surgery
 - Treating locally recurrent disease
 - Palliation management in unresectable tumors
- Chemotherapy used as palliation in patients with advanced disease:
 - Role of chemotherapy in treatment remains unproven.
 - No proven chemotherapeutic protocols

- Tumors measuring greater than 4 cm have a worse prognosis.
- Facial nerve paralysis:
 - Symptoms of facial nerve paralysis may be associated with worse prognosis and quicker demise of patient
- Histologic grade:
 - Tumors with tubular and cribriform growth have better prognosis:
 - 15-year survival rates:
 - Grade I: 39%
 - Grade II: 26%
 - Predominantly solid tumors (i.e., more than 30% of overall pattern) have worse prognosis associated with earlier and more frequent recurrent tumor.
 - Higher incidence of metastasis:
 - May metastasize even in clinically lower stage tumors (e.g., T1, T2)
 - Earlier fatal outcomes:
 - 14% 5-year survival
 - 5% 15-year survival
- Clinical stage:
 - Advanced clinical stage associated with poorer outcome
 - Stage I: 75% 10-year survival
 - Stage II: 43% 10-year survival
 - Stages III-IV: 15% 10-year survival
- Positive surgical margins and/or failure of local disease control following initial surgery:
 - Recurrent tumor is generally a sign of incurability.
- Adverse prognosis also associated with:
 - Presence of distant metastatic disease (5-year survival rate of 20%)
 - Presence of extranodal extension in nodal metastasis
 - Presence of osseous invasion
- Higher proliferative index (greater than 10% of tumor cells) as determined by Ki67 staining correlates to more aggressive tumors.

POLYMORPHOUS LOW-GRADE ADENOCARCINOMA OF MINOR SALIVARY GLANDS (PLGA)

(Figs. 20-82 through 20-89)

Definition: Malignant epithelial neoplasm characterized by cytologic uniformity, morphologic diversity, infiltrative growth pattern, and a low metastatic potential.

Synonyms: Terminal duct carcinoma; lobular carcinoma

- Terminology of “terminal duct” carcinoma was used to emphasize proposed histogenesis of the tumor, thought to be progenitor cell of the distal or terminal

duct portions of salivary gland unit (i.e., intercalated duct reserve cell).

- Terminology of “lobular” carcinoma was used because of presence of single cell–filling infiltrative growth pattern similar to that of lobular carcinoma of breast origin.

Clinical

- More common in women than in men; occurs over a wide age range from the second to tenth decades of life, but most frequently seen in the sixth to eighth decades of life:
 - Rarely occurs in the pediatric population
- Occurs primarily in minor salivary glands:
 - Almost exclusively identified in the oral cavity:
 - Approximately 60% to 70% involve palate (junction of hard and soft palate)
 - Other intraoral locations include buccal mucosa, upper lip, retromolar region, and base of tongue
 - Less common locations include parotid gland, lacrimal gland, nasopharynx, nasal cavity, sublingual, and submandibular glands:
 - May occur in parotid gland as malignant epithelial component in a carcinoma ex pleomorphic adenoma
- Most common symptom is that of a painless mass or swelling occasionally associated with bleeding, increase in size or discomfort; other less frequently identified symptoms include otalgia, odynophagia, tinnitus, and airway obstruction
 - Duration of symptoms is variable, ranging from as short as 2 weeks to a 20- to 30-year history of a mass lesion.
- Etiology:
 - No predisposing factors known to exist

Pathology

Gross

- Polypoid or raised, circumscribed to poorly demarcated, round to oval, mucosal-covered masses ranging in size from 1.0 to 6.0 cm in greatest dimension
- In general, overlying mucosa remains intact; however, surface ulceration may be present.

Fine-Needle Aspiration Biopsy

- Smears show high cellularity with a population of mixed epithelial and myoepithelial cells.
- Sheets and clusters of cells are seen and occasionally branching papillae may be identified.
- Epithelial cells appear cuboidal to spindle-shaped with uniform, round to ovoid nuclei with fine nuclear chromatin; absent or inconspicuous nucleoli; and a moderate amount of dense cytoplasm.

Fig. 20-82. High-grade transformation (dedifferentiation) of adenoid cystic carcinoma.

A, Transitional areas from differentiated adenoid cystic carcinoma characterized by cribriform growth and more uniform appearing cells (left of center) and areas of more disorganized growth (*right*). **B**, Higher magnification of the differentiated adenoid cystic carcinoma foci. **C**, Higher magnification of the histologically higher grade malignant component representing a high-grade adenocarcinoma. In relationship to the differentiated carcinoma there was **(D)** perineural invasion and **(E)** cervical lymph node metastasis.

Fig. 20-83. Polymorphous low-grade adenocarcinoma.

A and **B**, At low magnification these tumors are unencapsulated and infiltrative, composed of more than one growth pattern (i.e., polymorphous). **B**, A characteristic feature is the presence of a swirling pattern often located at peripheral aspects of neoplasm.

- Occasionally cells form spheric structures containing hyaline globules.
- Myxoid matrix either dispersed in the background or interspersed with the cellular elements can also be seen.

Histology

- At low magnification appears well circumscribed, but unencapsulated and infiltrative growth may be appreciated.
- Multiple growth patterns (i.e., polymorphism) identified, including tubular (glandular, ductular), trabecular, solid nests, targetoid swirls, cribriform, fascicular, single cell filing, cystic, and/or papillary:
 - These patterns may be identified between tumors and within an individual tumor.
 - Many salivary gland tumors are polymorphous so the presence of polymorphism is not diagnostic for PLGA or for that matter any other salivary gland tumor.

- Main microscopic patterns are:
 - Tubular (glandular, ductular):
 - Identifiable central lumens
 - Seen individually or in clusters
 - Complex tubuloglandular structures common
 - Seen throughout the lesion but may be prominent at periphery where they are seen infiltrating adjacent tissues
 - Trabecular:
 - May appear in streaming pattern with identifiable lumens
 - Targetoid swirls:
 - Best appreciated at lower magnification(s)
 - Often located at peripheral aspects of neoplasm
 - Swirls, concentric whorls or targetoid arrangements
 - Characteristic although not pathognomonic
 - May envelop blood vessels or surround nerves
 - Solid or lobular:
 - Often seen in the central portions of the tumor
 - Sometimes seen with peripheral palisading of columnar cells
 - Cribriform and/or microcystic:
 - Similar to adenoid cystic carcinoma
 - Single cell filing:
 - Refers to pattern of cell growth in which the cells are arranged in a single row
 - Not a consistently common finding
 - Often located at periphery of tumor
 - Papillary or papillary-cystic foci:
 - Usually not a predominant feature
 - Consists of dilated cystic spaces with or without intraluminal papillary projections
 - Less common patterns include fascicular and canalicular
- Lesional cells characteristically:
 - Small to medium-sized cuboidal to columnar isomorphic cells with indistinct cell borders and uniform ovoid to spindle-shaped nuclei with vesicular to stippled to minimally hyperchromatic (basophilic) nuclear chromatin, small to inconspicuous nucleoli, scant to moderate amounts of eosinophilic to amphophilic cytoplasm, and indistinct cell borders
 - Spindle-shaped cells may be identified.
 - Minimal to absent nuclear pleomorphism
 - Absent to low mitotic activity
 - Atypical mitoses uncommon
 - Necrosis is not a typical feature.
 - Occasionally other cell types may be seen, including:
 - Clear cells and mucinous cells
 - Less often oncocytic, squamous, or acinic cells may be found.

- Presence of myoepithelial cells is controversial:
 - Some reports document myoepithelial cells as integral component
 - Some reports document absence of myoepithelial cells or very focal presence of myoepithelial cells.
- Tumor stroma varies from mucoid to hyaline to mucohyaline:
 - Often has a slate gray appearance
 - In some cases tumor nests are separated by a fibrovascular stroma.

Fig. 20-84. Polymorphous low-grade adenocarcinoma.

A variety of growth patterns may be seen from case to case and even within a single case, including (A) tubular with focal cribriform (*arrowhead*); (B) microcystic; (C) solid; (D) single cell filing; (E) papillary;

Continued

Fig. 20-84, cont'd

(F) fascicular; and (G) canalicular.

Fig. 20-85. Polymorphous low-grade adenocarcinoma.

A and **B**, Irrespective of growth pattern, the neoplastic cells are rather uniform (isomorphic), with limited variation in size and shape, vesicular-appearing nuclei, inconspicuous to small nucleoli, and absence of mitotic activity or necrosis.
C, Mitotic figures (*arrowhead*) may occasionally be identified.

Fig. 20-86. Polymorphous low-grade adenocarcinoma.

A and **B**, The stroma tends to be myxoid or chondroid with a grayish appearance. **C**, Tyrosine-like crystals may be identified.

Fig. 20-87. Polymorphous low-grade adenocarcinoma.

Immunohistochemical staining is not typically required in diagnosing polymorphous low-grade adenocarcinoma. Among the markers seen include **(A)** haphazard p63 immunoreactivity including focal positive areas adjacent to negative areas; typically other myoepithelial markers are negative (not shown); **(B)** CD117 immunoreactivity may be present and is not a stain that consistently differentiates polymorphous low-grade adenocarcinoma from adenoid cystic carcinoma. A consistent marker seen in polymorphous low-grade adenocarcinoma is S100 protein (see next image).

Fig. 20-88. Polymorphous low-grade adenocarcinoma.

Invasive growth is a required feature in diagnosing polymorphous low-grade adenocarcinoma, which may include (A) perineural invasion (*arrowhead*) that may be readily identified by light microscopy but may require (B) S100 protein staining to confirm the presence of a peripheral nerve (*arrowhead*); note the tumor cells are diffusely and strong S100 protein positive. In addition to neurotropism, infiltrative growth may include invasion into (C) skeletal muscle or fat (not shown). D, Another characteristic although not pathognomonic finding is entrapment rather than effacement of residual minor salivary glands. Although not shown here, extension and involvement of the surface epithelium are not indications of invasion and should not be used as evidence of malignancy.

- Areas of hemorrhage may be present.
- Despite the innocuous cytologic appearance, neoplasm always invasive:
 - Neurotropism (peri- and intraneural) found in majority of tumors usually involving small to medium-sized nerves
 - Perivascular invasion can also be seen with tumor nests often arranged in concentric fashion around these structures.
 - Invasion of seromucous glands:
 - Envelopment but not effacement typical infiltrative pattern
 - Rather characteristic although not pathognomonic
 - Invasion of mature adipose tissue and/or skeletal muscle
 - Invasion of bone:
 - May be seen in tumors of palate or mandible
 - Extension and involvement of surface (squamous) epithelium may be present, but this finding is not considered evidence of invasive growth or diagnostic for malignancy
- Other changes that may be identified include:
 - Tyrosine-type crystalloids and psammoma bodies can be seen in some cases.
 - Pseudoepitheliomatous hyperplasia of surface (squamous) epithelium

Fig. 20-89. PLGA.

Rarely, transition to a higher histologic grade tumor may be seen in PLGA. **A**, PLGA with typical histology is seen on right transitioning to an area with greater nuclear pleomorphism and mitotic activity (*center and left*).

B, Higher magnification of the higher histologic grade (less differentiated) component of the tumor.

- Squamous metaplasia:
 - A feature that can be seen following fine-needle aspiration biopsy or incisional biopsy
- Histochemistry:
 - Intraluminal mucin can be identified by diastase-resistant, PAS-positive material
 - Intracytoplasmic mucin if present is focal and weakly stained by mucicarmine or PAS with diastase.
- Immunohistochemistry:
 - Cytokeratins, EMA, S100 protein, vimentin positive
 - Variable reactivity for CEA and muscle-specific actin (MSA)
 - p63 and p40:
 - Variable p63 reactivity but usually at least focally present
 - p40 usually negative
 - IHC findings including pairing p63 and p40 reported to assist in differentiating pleomor-

phic adenoma (PA) from polymorphous low-grade adenocarcinoma (PLGA) and adenoid cystic carcinoma (AdCC) include:

- PA: p63+/p40+
- Cellular PA: concordant p63+/p40+ or p63–/p40–
- PLGA: consistent p63+/p40–
- AdCC: p63+/p40+

CAUTIONARY NOTE: While p63/p40 IHC panel can be a valuable tool for making distinction between PA, PLGA, and AdCC it is not infallible and any given example may demonstrate divergence from the reported p63/p40 immunophenotype.

- Usually negative for other markers of myoepithelial cells including calponin, actins, smooth muscle myosin heavy chain
- GFAP typically negative
- May be reactive for mammaglobin and/or GCDFP15
- May occasionally be PLAG1 positive
- Variable c-kit (CD117), bcl-2, and galectin 3
- Low proliferative rate indices (less than 5%) by Ki67 staining
- Electron microscopy:
 - Glandular or duct-like structures, junctional complexes (desmosomes, tight junctions), lumina, and microvilli
- Cytogenetics and molecular genetics:
 - Somatic *PRKD1* hotspot mutations encoding p.Glu710Asp found in 73% of PLGAs but not in other salivary gland tumors emerging as a new cancer-related gene likely constituting a driver of PLGA:
 - Morphologic and molecular overlap with cribriform adenocarcinoma of minor salivary glands (see below) including the fact that these two tumors are driven by genes in the same family suggests they are closely related
 - CGH analysis revealed:
 - PLGA genome is genetically stable, containing comparatively few copy number alterations (CNAs)
 - In line with clinical observation that PLGA is a slow-growing, low-grade carcinoma with low metastatic potential
 - Absence of *MYB-NFIB* by RT-PCR analysis
 - Single reported case expressing *MYB-NFIB*
 - Absence of ETV6 translocation

High-Grade Transformation (“Dedifferentiation”) in PLGA

- Rare occurrence of a histologically typical PLGA with high-grade carcinoma component characterized by:
 - Nuclear atypia
 - Markedly increased mitotic activity

- Increased proliferation indices (Ki67 or MIB1 index)
- Prominent zones of necrosis
- High-grade component may resemble salivary duct carcinoma including immunoreactivity for androgen receptor
- Recent identification of high-grade tumor with morphologic, immunohistochemical and molecular features of PLGA and cribriform adenocarcinoma of minor salivary glands (referred to as high-grade polymorphous/cribriform adenocarcinomas) identified characterized by greater nuclear pleomorphism, increased mitotic activity, solid growth and necrosis with more aggressive behavior

Differential Diagnosis (Table 20-9)

- Pleomorphic adenoma:
 - In minor salivary gland sites is unencapsulated similar to PLGA but noninvasive unlike PLGA
- Monomorphic adenoma
- Adenoid cystic carcinoma:
 - Differentiation is predicated on light microscopic features because both tumors may show neurotropism and have overlapping immunohistochemical findings.
 - Presence of isomorphic cells composed of small angulated hyperchromatic nuclei that characterize adenoid cystic carcinoma contrast to the isomorphic round to oval, vesicular nuclei of PLGA.
 - More pronounced cribriform component
 - Presence of *MYB-NFIB* fusion would support diagnosis of adenoid cystic carcinoma.
- Cribriform adenocarcinoma (see below):
 - Based on differences in morphology and, more importantly, biologic behavior (local recurrence, cervical lymph node and distant metastases, and mortalities directly related to neoplasm) should be considered a distinct and separate entity from PLGA.

Treatment and Prognosis

- Treatment includes complete surgical excision in as conservative a manner as to ensure tumor-free margins:
 - Invasion of bone may necessitate more extensive surgical resection that may include maxillectomy or en bloc resection of mandible.
- Limited (if any) utility for radiation or chemotherapy
- Neck dissection is not indicated unless there is evidence of cervical adenopathy.
- Overall prognosis is excellent:
 - Indolent behavior
 - 95% 10-year survival
 - Local recurrence rate between 9% and 17%:

- Due to its slow growth rate, local recurrence typically occurs several years following initial treatment.
- Regional metastatic rate from 9% to 15%:
 - Similar to local recurrence, may occur several years following initial treatment
- Distant metastases seldom reported
- Death attributed to tumor is unusual and occurs after prolonged periods
- Papillary architecture may be associated with more aggressive behavior:
 - Increased incidence of recurrence
 - Increased incidence of regional (cervical nodal) and distant metastasis
 - No increase in mortality
 - Such neoplasms may in fact be cribriform adenocarcinomas of minor salivary glands (see below)
- PLGA may occur as malignant component in carcinoma ex pleomorphic adenoma:
 - In setting of carcinoma ex pleomorphic adenoma:
 - Better prognosis than other types of carcinomas arising in pleomorphic adenoma
 - More aggressive than de novo PLGA
- Histologic high-grade transformation of an otherwise typical PLGA may rarely occur:
 - See previous discussion.
- Some consider polymorphous low-grade adenocarcinoma the low-grade variant of adenoid cystic carcinoma based on the morphologic similarities as well as common derivation from intercalated duct region; however, there is no support for this consideration.
- Cribriform adenocarcinoma of minor salivary glands previously considered a variant of PLGA but now recognized as a separate tumor type (see below)

CRIBRIFORM ADENOCARCINOMA OF MINOR SALIVARY GLANDS (CAMSG) (Fig. 20-90)

Definition: Submucosal invasive adenocarcinoma with cribriform, tubular/glandular, and papillary growth, nuclear features reminiscent of thyroid papillary carcinoma, and tendency to be associated in a high percentage of cases with nodal metastasis.

Synonyms: Cribriform adenocarcinoma of the tongue and minor salivary glands (CATSMG)

Clinical

- Slightly more common in women than in men; occurs in adults over a wide age range from 21 to 85 years with a mean of 56.8 years

TABLE 20-9 PLGA and Other Intraoral Salivary Glands Neoplasms: Selective Differential Diagnosis

Tumor	Capsule, Invasion	Growth Patterns	Cytomorphology	Stroma	IHC	Cytogenetic
PLGA	Absent and infiltrative	Polymorphic, including tubular/ductules, cribriform, solid, linear single cell, "streaming" along periphery, papillary	Isomorphic cells with minimal pleomorphism; no necrosis or increased mitotic activity; intercellular hyaline material may be present	Slate gray myxoid; crystalloids may be present	Positive for epithelial and myoepithelial markers: CKs, p63, S100 protein, others; p40 negative*; low proliferation indices	None known although <i>PRKD2</i> rearrangement reported in a single case
PA	Absent but well circumscribed	Polymorphic, including tubules, ribbons, sheets, cords, cysts, trabeculae	Dual cell population: ducts/glands and myoepithelial cells; no necrosis or increased mitotic activity; intercellular hyaline material may be present	Chondromyxoid; crystalloids may be present	Positive for epithelial and myoepithelial markers: CKs, p63, p40, S100 protein, others; low proliferation indices	<i>PLAG1</i> <i>HMG2A</i>
CPA (E or M)	Absent but well circumscribed	Polymorphic, including tubules, ribbons, sheets, cords, cysts, trabecular, fascicular, anastomosing cords	Dual cell population: ducts/glands and myoepithelial cells; for myoepithelial predominant tumors lesional cells include spindle-shaped and plasmacytoid cells but ducts/glands focally seen; no necrosis or increased mitotic activity; intercellular hyaline material may be present	Scanty but identifiable chondromyxoid stroma; crystalloids may be present	Positive for epithelial and myoepithelial markers: CKs, p63, S100 protein, others; low proliferation indices	<i>PLAG1</i> <i>HMG2A</i>
AdCC, tubular, cribriform	Absent and infiltrative	Polymorphic, including cribriform, tubular/ductules, islands, cysts, nests, cords, solid	Basaloid cells with uniform, angulated, hyperchromatic nuclei, scanty cytoplasm; no necrosis or increased mitotic activity; intercellular hyaline material present	Myxoid-hyaline stroma	Positive for epithelial and myoepithelial markers: CK, p63, p40, S100 protein, others; increased proliferation indices [†]	<i>MYB-NFIB</i>
CAM SG	Absent and infiltrative	Cribriform, tubular/glandular papillary and solid growth patterns; often divided into lobules by fibrous septa	Lesional cells include round to oval to elongated nuclei with irregularities in size and shape, clear to very fine-appearing nuclear chromatin; nuclear grooves and nuclear pseudoinclusions (reminiscent nuclei in papillary thyroid carcinoma); mild to focally moderate nuclear pleomorphism may be present but no substantial increase in mitotic activity and no necrosis	No specific stromal component; calcifications including psammomatoid concretions may be present	Strong reactivity for cytokeratins (AE1/AE3, CAM5.2, CK7, CK8, CK18), S100 protein, and vimentin; variable reactivity for p63, calponin, CK14, smooth muscle actin, CK5/6; negative for thyroglobulin and TTF1; significant reactivity for CD117 (cytoplasmic and membranous); low proliferation	Recurrent <i>PRKD1-3</i> rearrangement

*p40 not necessarily consistently negative in PLGA or positive in the other neoplasms.

[†]Increased proliferation indices may not be present in all cases of AdCC and by itself does not definitively differentiate it from PA, cellular PA, and PLGA.

AdCC, Adenoid cystic carcinoma; CAMSG, cribriform adenocarcinoma of minor salivary glands; CKs, cytokeratins; CPA, cellular pleomorphic adenoma; E, epithelial predominant; M, myoepithelial predominant; PA, pleomorphic adenoma; PLGA, polymorphous low-grade adenocarcinoma.

Fig. 20-90. Cribriform adenocarcinoma of minor salivary glands.

A, Submucosal unencapsulated and invasive neoplastic proliferation; intact squamous epithelium is present (*extreme left*). **B**, Neoplastic proliferation comprised of lobules separated by fibrous septa showing cribriform and solid growth patterns; intraluminal eosinophilic secretions are seen. **C**, Lesional cells show nuclear features reminiscent of those seen in papillary thyroid carcinoma (solid variant) including round to oval to elongated nuclei with irregularities in size and shape, clear to very fine-appearing nuclear chromatin. **D**, Tumor nests detached from surrounding fibrous stroma by clefts imparting a glomeruloid appearance.

- Most common site of occurrence is tongue:
 - Base of tongue a frequent location
 - Other intraoral sites of occurrence include soft palate, buccal mucosa, tonsil, lip
 - May occur outside the oral cavity including major salivary glands
- Presentation may include:
 - Intraoral mass
 - Not infrequently may present with enlarged lateral neck mass
- Etiology:
 - No known associated causes

Pathology

Gross

- Unencapsulated lesion with tan-gray to white color and firm to hard consistency

Fine-Needle Aspiration Biopsy

- Aspirates contain polymorphic fragments of epithelial cells arranged in monolayer sheets, papillary fronds and tips, and occasional cribriform configurations.
- Metachromatic stromal fragments may be identified and may be misinterpreted as colloid.
- Background myxoid/mucoid material reminiscent of colloid may be prominent.

Histology

- Submucosal unencapsulated and invasive adenocarcinoma with cribriform, tubular/glandular, papillary, and solid growth patterns:
 - Often divided into lobules by fibrous septa
- In solid areas, tumor nests may be detached from surrounding fibrous stroma by clefts (presumably

artifactual) imparting a somewhat glomeruloid appearance:

- Peripheral layer of such solid tumor nests often displays hyperchromatic nuclei in a vaguely palisaded pattern
- Lesional cells include round to oval to elongated nuclei with irregularities in size and shape, clear to very fine-appearing nuclear chromatin, and nuclear grooves:
 - Nuclear features somewhat reminiscent of those seen in papillary thyroid carcinoma (solid variant)
 - Intranuclear inclusions may be identified.
- Mild to focally moderate nuclear pleomorphism may be present but with no substantial increase in mitotic activity and no necrosis.
- Calcifications, including psammomatoid concretions, may be present.
- Intraluminal mucinous-appearing secretions may be present.
- Infiltrative growth may include perineural invasion, lymph-vascular invasion, and invasion into soft tissues including skeletal muscle.
- Intact overlying squamous epithelium often identified:
 - Typically no ulceration present
 - Pseudoepitheliomatous hyperplasia may be present.
 - No evidence of intraepithelial dysplasia and/or carcinoma in situ
- Histochemistry:
 - Intraluminal secretions diastase-resistant, PAS-positive, and weakly mucicarmine positive
- Immunohistochemistry
 - Strong reactivity for cytokeratins (AE1/AE3, CAM5.2, CK7, CK8, CK18), S100 protein, and vimentin
 - Variable reactivity for basal/myoepithelial cell markers including p63, calponin, CK14, smooth muscle actin, CK5/6
 - May be reactive for galectin-3, CK19, and HBME-1 but negative for thyroglobulin and thyroid transcription factor 1 (TTF1)
 - Significant reactivity for c-kit (CD117), including strong cytoplasmic and membranous expression, may be present in from 10% to 80% of lesional cells.
 - p16 staining (cytoplasmic and nuclear) may be present but typically with patchy pattern in majority of cases considered nonreactive; rare cases reported as diffusely reactive
 - Negative for EMA, epidermal growth factor receptor, *HER-2/neu*, estrogen receptor, and progesterone receptor negative
 - Negative mammaglobin and c-kit
 - Low proliferation indices (less than 5%) by Ki67 staining

- Cytogenetics and molecular genetics:
 - Novel and recurrent gene rearrangements in *PRKD1-3* identified, suggesting possible pathogenic dichotomy from PLGA
 - Presence of cases with similar genetic findings considered “indeterminate” for CAMSG and PLGA as well as activated E710D hotspot mutation in *PRKD1* in 73% of PLGAs suggests shared pathogenesis between CAMSG and PLGA
 - No mutations of *RET*, *BRAF*, *KRAS*, *HRAS*, *NRAS*, *c-kit*, and *PDGFRA* genes
 - Negative for high-risk/low-risk HPV types:
 - In one reported case high-risk HPV type 33 detected (this case also showed weak positivity of HPV type 18)

Differential Diagnosis

- Polymorphous low-grade adenocarcinoma
- Adenoid cystic carcinoma
- Metastatic thyroid papillary carcinoma

Treatment and Prognosis

- Complete surgical resection to include tumor-free margins is indicated.
- Regional (cervical) lymph node metastasis:
 - High frequency (65%) at presentation
 - Should necessitate neck dissection as part of initial treatment protocol
- Highly favorable prognosis:
 - Majority of patients alive without disease or alive with recurrent disease over periods ranging from 2 months to 13 years (median follow-up of 6 years 5 months)
 - Prognosis does not appear to be altered by presence of nodal metastasis.

MALIGNANT MIXED TUMORS OF SALIVARY GLANDS

- Following lesions are grouped within this category:
 - Carcinoma ex pleomorphic adenoma
 - Noninvasive or intracapsular carcinoma ex pleomorphic adenoma
 - True malignant mixed tumor or carcinosarcoma
 - Metastasizing pleomorphic adenoma

Carcinoma Ex Pleomorphic Adenoma (CEPA) (Figs. 20-91 through 20-94)

Definition: Malignant transformation of a pre- or coexisting pleomorphic adenoma with infiltrative growth:

- By definition this tumor type lacks evidence of a co-existing mesenchymal malignancy (i.e., sarcoma)

Fig. 20-91. Carcinoma ex pleomorphic adenoma.

Carcinoma ex pleomorphic adenoma, high-grade, appearing as a huge, fungating mass completely obliterating and distorting the patient's normal facial structures.

- May be identified in association with histologic evidence of a pleomorphic adenoma
- Arises in a site previously involved by a pleomorphic adenoma

Synonym: Carcinoma ex mixed tumor

Clinical

- Accounts for approximately 12% of all malignant salivary gland neoplasms, 4% to 6% of all pleomorphic adenomas, and 2% to 4% of all salivary gland neoplasms
 - Of entities included under the designation malignant mixed tumors of salivary glands, more than 90% are (invasive) carcinoma ex pleomorphic adenomas.
- No gender predilection; may be seen over a wide age range but most frequently occurs in the sixth to seventh decades of life:
 - Occur approximately one decade older than patients with pleomorphic adenomas
 - Extraordinarily rare in infants and young children
- Sites of occurrence:
 - Most commonly occurs in major salivary glands:
 - Parotid gland > submandibular gland
 - May occur less often in minor salivary glands
 - Palate most commonly involved minor salivary gland site
 - Rarely occurs in sublingual gland
- Typical clinical presentation includes sudden or rapid enlargement of a long-standing painless, non-enlarging or slowly enlarging mass over a short time period (e.g., 3- to 6-month period)
 - Associated symptoms may include pain, facial nerve paresis or paralysis, soft tissue fixation

(especially in patients with recurrent tumors), and regional lymphadenopathy.

- Time period for malignant transformation of pleomorphic adenoma (initial or recurrent) may be from 2 to 50 years but on average is approximately 20 years:
 - Risk of malignant transformation increases with duration of tumor:
 - 1.6% for tumors less than 5 years
 - 9.5% for tumor present for more than 15 years

Pathology

Gross

- Appearance may depend on histologic grade:
 - Most are histologically high grade and appear as poorly circumscribed to overtly infiltrative masses with tan-white appearance and firm to hard consistency:
 - Areas of hemorrhage, necrosis, cystic change, and softening of the tissue may be present.
 - Occasionally high-grade CEPA may be circumscribed and/or encapsulated (see intracapsular CEPA below)
 - Histologically low-grade CEPAs may appear poorly circumscribed to overtly infiltrative or may show similarities to pleomorphic adenoma, including circumscription or encapsulation.
- May range in size from 1 to 17 cm in greatest dimension
- Residual foci of pleomorphic adenoma may be identified, appearing as glistening to fibrotic (nodular) foci

Fine-Needle Aspiration Biopsy

- Unequivocal malignant epithelial cells admixed with benign epithelial and stromal components of pleomorphic adenoma are considered diagnostic by FNAB:
 - In most aspirates epithelial cells predominate over stromal components.
 - Necrosis and mitotic figures, including atypical forms, may be seen.
- Aspirates may be cellular and include epithelial cells with atypia characterized by mild to moderate degree of pleomorphism, absence of unequivocal malignant cells, and a variable proportion of benign epithelial and stromal components.
- Sampling error is important cause of diagnostic pitfalls:
 - Correlation with clinical findings is essential in FNAB diagnosis.
 - In appropriate clinical setting (i.e., rapid enlargement of a long-standing salivary gland tumor), any degree of nuclear atypia should be documented and should raise concern for a possible

Fig. 20-92. Carcinoma ex pleomorphic adenoma, high-grade.

A, Transition between residual pleomorphic adenoma (*top*) characterized by benign glandular structures and chondromyxoid stroma to areas with more complex glandular growth pattern and marked nuclear pleomorphism (*lower*). **B**, Area of residual pleomorphic adenoma characterized by acellular hyalinization with benign tubules. **C** and **D**, The malignant component often is a high-grade adenocarcinoma with features similar to those of salivary duct carcinoma including cribriform growth with comedotype necrosis and cells with marked nuclear pleomorphism and increased mitotic activity; lesional cells were androgen receptor positive (not shown). Typically there is extensive invasive growth including (**E**) into adjacent salivary gland parenchyma, *Continued*

Fig. 20-92, cont'd

(F) perineural invasion, and (G) lymph-vascular invasion (note the features of squamous cell carcinoma).

Fig. 20-93. Carcinoma ex pleomorphic adenoma, low-grade.

A, This man had previous excision of a pleomorphic adenoma (note scar anterior to the ear) with recurrence and recent enlargement of the recurrent tumor. **B** and **C**, The recurrence was a myxoid-predominant pleomorphic adenoma within which was another type of neoplastic proliferation characterized by tubular growth and cells with prominent basophilic cytoplasmic granules and vacuolated cells; these cells were DOG1 positive (not shown). The findings are those of an acinar cell carcinoma ex pleomorphic adenoma.

Fig. 20-94. Carcinoma ex pleomorphic adenoma, low to intermediate grade.

A, This patient had multiple recurrences of a palatal mass most recently with rapid increase in size and evidence of bone invasion by radiologic imaging; a biopsy (not shown) confirmed the presence of tumor in bone, necessitating radical excision. **B**, At low magnification the tumor is extensively infiltrative into palatal bone. **C**, Residual foci of a myoepithelial-predominant (plasmacytoid) pleomorphic adenoma were present. **D**, Areas of the tumor showed increased nuclear pleomorphism with prominent nucleoli, scattered mitoses, and stromal hyalinization. Immunohistochemical staining showed the neoplastic cells to be reactive for **(E)** cytokeratin (AE1/AE3), **(F)** calponin,

Continued

Fig. 20-94, cont'd

(G) p63, and (H) S100 protein. The findings in this case are those of a myoepithelial carcinoma ex pleomorphic adenoma.

diagnosis that may necessitate additional FNAB.

Histology

- Carcinomatous component may be histologically high grade or lower grade:
 - Carcinoma in most cases is histologically high grade, characterized by enlarged cells with marked nuclear pleomorphism, nuclear hyperchromasia, prominent nucleoli, increased mitotic activity with atypical mitoses and necrosis.
 - High-grade carcinomas are most often:
 - Salivary duct carcinoma or high-grade adenocarcinoma, not otherwise specified
 - Less often tumor types include undifferentiated carcinoma, squamous cell carcinoma, adenosquamous carcinoma, sarcomatoid carcinoma, small cell carcinoma, oncocytic carcinoma
 - In a significant minority of cases the carcinoma is histologically low grade with carcinoma defined on basis of recognition into a specific type of salivary gland carcinoma and/or evidence of infiltrative growth.
 - Histologically lower-grade carcinomas include:
 - Low- to intermediate-grade adenocarcinoma, NOS, myoepithelial carcinoma, mucoepidermoid carcinoma, polymorphous low-grade adenocarcinoma, acinic cell adenocarcinoma, epithelial-myoepithelial carcinoma, adenoid cystic carcinoma
 - Rare example of melanoma arising in carcinoma ex pleomorphic adenoma reported
- Invasive growth is present, including invasion into adjacent salivary gland parenchyma, fibroconnective tissue (e.g., skeletal muscle, adipose tissue, others), neurotropism (peri- and intraneural), and lymphovascular angioinvasion.
- Evidence of pleomorphic adenoma:
 - Proportion of pleomorphic adenoma in any given case varies from being readily identifiable to cases in which it is difficult to identify appearing hypocellular or hyalinized without cellularity.
 - Foci of pleomorphic adenoma and carcinoma may be demarcated from one another or two components may be intimately admixed.
 - Transition areas between benign and malignant foci may be present.
 - Evidence of (residual) pleomorphic adenoma may include presence of:
 - Classic foci including combination of benign tubular or ductular structures, myoepithelial cells, and chondromyxoid stroma
 - Hyalinized (nodular) stroma:
 - May contain identifiable benign tubular or ductular structures with bland cytomorphology and dual cell (epithelial and myoepithelial) differentiation by light microscopy and/or immunohistochemical staining
 - May be acellular:
 - Extensive hyalinization in a pleomorphic adenoma has been shown to be associated with increased risk for malignant transformation, and presence of hyalinized focus/nodule near to a malignancy is evidence of residual pleomorphic adenoma supporting diagnosis of CEPA.
 - Numerous sections may be required to identify foci of residual pleomorphic adenoma.

- Immunohistochemistry:
 - *HER-2* expression, p53 expression, androgen receptor, and Ki67 labeling index higher in carcinomatous component
 - S100 protein overexpression reported to be significantly more prevalent in carcinomatous component than in pleomorphic adenoma with or without atypical features
 - Results suggest that S100 protein immunohistochemical staining may be useful diagnostic marker for identifying the early phase of carcinoma ex pleomorphic adenoma in combination with *HER-2*, p53, androgen receptor, and Ki67
 - *PLAG1* staining may be present but FISH appears to be more sensitive than IHC staining in detecting *PLAG1* abnormalities.
- Cytogenetics and molecular genetics:
 - Most CEPAs regardless of morphologic subtype carry altered *PLAG1* or *HMGA2* genes
 - FISH for *PLAG1* and *HMGA2*:
 - CEPAs reported positive for *PLAG1* or *HMGA2* rearrangements/amplifications
 - Represent the most common genetic events in CEPA regardless of histologic subtype
 - Rearrangements of *PLAG1/HMGA2* identified in most hypocellular PAs but only in a small subset of cellular PAs
 - De novo carcinomas reported negative for *PLAG1* and *HMGA2*
 - *HER2* gene amplification found in up to 82% of cases
 - More common in presence of cases with extracapsular invasion than without invasion
 - Alterations in *TP53* gene and p53 protein overexpression identified in up to 67% and 75% of cases, respectively:
 - Involved in the early stages of malignant transformation of PA
 - LOH at microsatellite loci on 8q and 12q in benign and malignant components and 17p in the malignant component
 - Rearrangements of 8q12 and 12q13-15 frequently identified
- Major glands:
 - Usually radical extirpation with sacrifice of facial nerve
- Minor glands:
 - Complete excision with tumor-free margins, which may necessitate removal of a portion of the mandible or maxilla.
- Due to a high rate of nodal metastasis, cervical lymph node dissection usually performed
- Adjunctive radiotherapy used for extensively invasive tumors, as well as in conjunction with surgery:
 - Radiotherapy in conjunction with surgery plays a beneficial role in preventing local recurrence.
- Chemotherapy is of questionable benefit.
- Associated with high recurrence and metastatic rates:
 - Recurrence rates (one or more) vary from 23% to 53%
 - Majority of recurrences develop within 5 years from the diagnosis, although recurrences decades later may occur.
 - Palatal CEPA tends to recur less often than CEPA of major salivary glands.
 - Metastatic rates (local and metastatic) vary and have been reported as high as 70%.
 - Metastases most frequently occur to regional lymph nodes, lungs, brain, and bone (vertebral column).
- In general, prognosis is poor especially in patients with local recurrence, regional metastasis, or distant metastasis:
 - Following the discovery of metastatic disease, death usually follows within 1 year.
- Survival rates include:
 - 5-year range from 25% to 65%
 - 10-year range from 24% to 50%
 - 15-year range from 10% to 35%
 - 20-year range from 0 to 38%
- Low-grade CEPA:
 - Wide surgical excision is the preferred treatment.
 - Unless there is clinical evidence supporting nodal metastases, then neck dissection may not be necessary.
 - Adjunctive radiotherapy in combination with surgery may be beneficial if the tumor is extensively invasive.
 - Prognosis for these tumors is considered to be much better than for histologically high-grade CEPA.
- Factors adversely affecting prognosis include:
 - Origin in major salivary gland
 - Recurrent and/or metastatic disease (locoregional, distant)

Differential Diagnosis

- Cellular pleomorphic adenoma
- Atypical pleomorphic adenoma
- Intracapsular CEPA (see below)
- Salivary duct carcinoma
- True malignant mixed tumor (see below)

Treatment and Prognosis

- For high-grade CEPA:
 - Wide surgical excision is the preferred treatment:

- Higher T stage
- Presence of neurotropism
- Histologic grade:
 - High-grade CEPAs have worse prognosis than low-grade CEPAs.
- Presence of *HER-2* gene amplification
- Surgical margins:
 - Presence of tumor-positive margins associated with higher recurrence rates and tumor-associated mortality rates than tumor-free margins; presence of tumor-free margins does not exclude the possibility of recurrence, metastasis, or tumor-related death.
- Extent of invasion:
 - Arguably most important prognostic factor
 - Discrepant findings in literature relative to distance defining better or worse prognosis including:
 - Invasion beyond 8 mm from the capsule associated with a poor outcome (i.e., died of disease)
 - Invasion greater than 1.5 mm portended worse outcome (e.g., shorter survival) than invasion less than 1.5 mm from capsule
 - Threshold for distinguishing minor extracapsular invasion with good prognosis from wide extracapsular invasion with poor prognosis is 5 mm
 - Patients with minimally invasive tumor have more favorable outcome than patients with widely invasive neoplasm.
 - Minimally invasive carcinoma ex pleomorphic adenoma can recur and can cause death.
- Presence of myoepithelial carcinoma subtype reported to increase risk of recurrence in carcinoma ex pleomorphic adenoma, especially within the group of minimally invasive tumors

Noninvasive or Intracapsular Carcinoma Ex Pleomorphic Adenoma (Fig. 20-95)

Definition: Salivary gland tumor showing histologic evidence of pleomorphic adenoma with unequivocal evidence of cytologic malignancy entirely confined to within the capsule without invasive growth.

Synonyms: Early carcinoma ex pleomorphic adenoma; intratubular carcinoma ex pleomorphic adenoma; carcinoma in situ ex pleomorphic adenoma

- Carcinoma in situ represents earliest phase of malignant transformation, characterized by carcinoma within ductal luminal cells, retention of myoepithelial cell layer, and absence of stromal invasion.

- Findings akin to ductal carcinoma in situ (DCIS) of the breast

Clinical

- Uncommon lesion with greater recognition in literature
- Demographics, including gender and age, are similar to pleomorphic adenoma.
- Clinical features at the initial diagnosis that may indicate a greater likelihood of malignant transformation include:
 - Occurrence in the submandibular gland
 - Older patient age
 - Larger tumor size
- Generally thought to represent early stage development in malignant transformation of a pleomorphic adenoma

Pathology

Gross

- Similar to pleomorphic adenoma

Histology

- Residual foci indicative of a pleomorphic adenoma are present, which may include benign glands or ducts, myoepithelial cells, chondromyxoid stroma, and/or hyalinized areas.
- Carcinomatous element composed of overtly malignant cells with enlarged, pleomorphic, and hyperchromatic nuclei with increased nuclear-to-cytoplasmic ratio, prominent nucleoli, and high mitotic rate.
 - To date, no reported instances of low-grade intracapsular CEPA
 - In theory such tumor types may occur composed of residual pleomorphic adenoma and identifiable malignancy purely based on cell type(s); examples could include:
 - Adenoid cystic carcinoma, acinic cell carcinoma, low-grade mucoepidermoid carcinoma, epithelial-myoepithelial carcinoma
 - May also include examples of carcinoma in situ
- By definition there is no evidence of invasion beyond the capsule of the tumor.
- Extensive sampling of the tumor, which may require submission of the entire tumor, should be performed to ensure that extracapsular involvement has not occurred.
- Immunohistochemistry:
 - Carcinomatous component strongly positive for *HER-2*
 - Cells of the maternal PA negative for *HER-2*
- Cytogenetics and molecular biology
 - Amplification of *HER-2/neu* gene signals in non-invasive carcinoma cells:

Fig. 20-95. Noninvasive carcinoma ex pleomorphic adenoma.

Noninvasive (intracapsular) carcinoma ex pleomorphic adenoma. **A** and **B**, Areas of this encapsulated parotid tumor showed foci of pleomorphic adenoma characterized by benign tubules with dual cell population within a variable appearing stroma including acellular hyalinization (**A**) and chondromyxoid appearing (**B**). **C** and **D**, Elsewhere in this neoplasm there were foci of high-grade carcinoma with features of salivary duct carcinoma (**C**) and squamous cell carcinoma (**D**). **E**, The entire tumor was submitted for histologic evaluation, showing it to be completely encapsulated without evidence of invasive growth.

- Less common than in cases with extracapsular invasion
- Alterations in *TP53* gene and p53 protein overexpression
- Involved in the early stages of malignant transformation of PA

Differential Diagnosis

- Atypical pleomorphic adenoma:
- Recurrent pleomorphic adenoma:
 - May be multinodular and/or include one or more nodules in the soft tissues of the neck

Fig. 20-96. Carcinosarcoma.

Carcinosarcoma appearing as huge parotid tumor completely distorting this patient's face.

- Nodules usually discrete and circumscribed without cytologic atypia

Treatment and Prognosis

- Treatment includes complete surgical excision.
- Adjunctive therapy likely unnecessary.
- Prognosis appears to be good.
 - Typically without metastatic potential
 - Single reported case with cervical lymph node metastasis
 - Another case reported of parotid gland neoplasm that recurred after interval of 8 years composed solely of pleomorphic adenoma that 5 years later recurred in the same site as myoepithelial carcinoma without evidence of ductal carcinoma as was reported in the initial intracapsular carcinoma ex pleomorphic adenoma

Carcinosarcoma (Figs. 20-96 and 20-97)

Definition: Malignant salivary gland neoplasm consisting of an admixture of malignant epithelial (carcinomatous) and malignant mesenchymal (sarcomatous) components.

Synonym: True malignant mixed tumor

Clinical

- Rare salivary gland neoplasm
- No gender predilection; most commonly seen in the sixth decade of life
- May occur in major and minor salivary glands:
 - Majority (two thirds of cases) occurs in parotid gland
 - Remainder of cases arise in submandibular gland and minor salivary glands:

Fig. 20-97. Carcinosarcoma.

A, At low magnification there are two histologically distinct areas including solid-appearing (*left*) and more lightly staining nodular/lobular area (*right*). **B,** At higher magnification there is an admixture of carcinomatous and sarcomatous components, including carcinoma with squamous and glandular features (*left and bottom*) and chondrosarcoma (*center and upper right*).

- Among minor salivary glands, palate is most frequent site of occurrence
- Most common symptoms relate to an enlarging mass with recent increase in size with or without associated pain and/or facial nerve paralysis.
- In general, these tumors arise *de novo*; however, some arise in association with a pleomorphic adenoma and are termed carcinosarcoma ex pleomorphic adenoma:
 - In association with a pleomorphic adenoma, clinical situation may include a long-standing mass lesion with recent/sudden rapid increase in growth.
 - May develop decades following radiation therapy for benign pleomorphic adenoma, but no clear link between radiotherapy and development of carcinosarcoma
- Histogenesis subject of controversy, but most authorities consider it to be of epithelial cell and

myoepithelial cell origin, the latter giving rise to the sarcomatous component:

- Pleomorphic adenomas consisting of an admixture of epithelial and mesenchymal-appearing tissue originate from epithelial and myoepithelial cells.
- Sarcomatous component derived from modulation of modified myoepithelial cells in similar manner to modulation of myoepithelial cells in benign pleomorphic adenomas producing chondromyxoid stroma

Pathology

Gross

- Unencapsulated to poorly circumscribed to infiltrative lesion measuring from 2 to 13 cm in greatest dimension
- Cut section may show a tan-gray to yellow, predominantly solid lesion with hemorrhage, necrosis, and calcification; cystic areas may be present.

Histology

- Biphasic appearance composed of carcinomatous and sarcomatous elements; sarcomatous component usually is dominant component
- Sarcomatous component:
 - Usually chondrosarcoma
 - Other malignant mesenchymal elements may include osteosarcoma, fibrosarcoma, malignant fibrous histiocytoma, leiomyosarcoma, liposarcoma, rhabdomyosarcoma, myxosarcoma, and malignant giant cell tumor.
 - Rarely, nonmalignant osteoid may be seen.
- Carcinomatous component:
 - Epithelial component is usually adenocarcinoma or squamous cell carcinoma.
 - Other malignant epithelial elements may include salivary duct carcinoma, undifferentiated carcinoma, adenoid cystic carcinoma, epithelial-myoepithelial carcinoma, and papillary cystadenocarcinoma.
- Cases occurring in association with a pleomorphic adenoma or in a site of previously excised pleomorphic adenoma show histologic evidence of coexisting pleomorphic adenoma or evidence of a pleomorphic adenoma in prior resection material.
- Immunohistochemistry:
 - Sarcomatous components:
 - Vimentin reactivity
 - Depending on the cell type, immunoreactivity may be present for:
 - Myogenic markers (desmin, myoglobin, myogenin, actins) for tumors with muscle (skeletal or smooth muscle) differentiation
 - S100 protein in chondrosarcoma
 - Carcinomatous components:
 - Cytokeratin positive

– Myoepithelial differentiation:

- p63, calponin, S100 protein, vimentin, smooth muscle actin, glial fibrillary acidic protein

Differential Diagnosis

- Carcinoma ex pleomorphic adenoma
- Spindle cell squamous carcinoma
- Salivary duct carcinoma, sarcomatous variant
- Synovial sarcoma
- Sarcoma, primary or metastatic

Treatment and Prognosis

- Complete surgical excision is preferred treatment:
 - Due to locally infiltrative and destructive growth radical surgery is usually necessary.
- Lymph node dissection is used for palpable disease.
- Adjunct radiotherapy is used to control local disease.
- Role of chemotherapy unproven but used in cases with metastatic disease
- Prognosis is poor:
 - Highly lethal neoplasms with mean survival of less than 30 months
 - Majority of patients die from disease.
 - Recurrent disease occurs in a majority of patients:
 - Recurrences include both histologic components.
 - Metastases occur in half the patients:
 - Metastases including both histologic components or may be restricted to the carcinomatous or sarcomatous component
 - Hematogenous spread most common with metastases most frequently to the lungs; other sites of metastases occur to liver, bone, brain, and lymph nodes (cervical and hilar)

Metastasizing Pleomorphic Adenoma (Fig. 20-98)

Definition: Salivary gland neoplasm with histomorphologic features of a pleomorphic adenoma but that metastasizes:

- Metastatic foci are histologically similar (i.e., benign) to the primary and/or recurrent neoplasms
- Due to potential for increased mortality designation “benign” has been eliminated.

Clinical

- Extremely rare
- No gender predilection; wide age range but the age at the time of primary tumor is in the third decade and in the seventh decade for metastatic tumor
- Primary neoplasm most frequently originates in parotid gland:
 - Other sites include the submandibular gland, intraoral minor salivary glands (most often the palate), and sinonasal seromucous glands.

Fig. 20-98. Metastasizing pleomorphic adenoma.

All these examples occurred in different patients all with tumor recurrence (at least one but usually multiple) of major or minor salivary gland pleomorphic adenomas, in which the primary tumor, recurrent tumor, and metastatic foci retained histologic features of usual pleomorphic adenoma without cytomorphic evidence of malignant transformation. **A** and **B**, Cervical lymph node metastasis; **C** and **D**, metastasis to the lung; **E** through **G**, metastasis to the humerus,

**Fig. 20-98, cont'd**

H and **I**, metastasis to the skull; and **J** through **L**, metastasis to the kidney.

- Clinical presentation of primary salivary gland tumor is that associated with pleomorphic adenomas:
 - Absence of clinical presentation/scenario associated with carcinoma ex pleomorphic adenoma (i.e., rapid enlargement in tumor size, pain, neuropathies)
- Typically, multiple recurrent pleomorphic adenomas are seen within the area of the primary tumor prior to development of metastases:
 - Rarely metastatic foci may represent initial clinical manifestation.
- Clinical presentation of metastasis dependent on site of metastatic disease and may include:
 - Neck mass or swelling, pain, pathologic fracture, space-occupying lesion
 - Metastasis may occur at the time of initial salivary gland tumor, but more often occur at the time of the recurrent tumor(s) and/or from years to decades later.

- Metastatic spread is by hematogenous and lymphatic routes with metastatic foci seen in bone (femur, humerus, pelvis, ribs, calvarium), lung, kidney, retroperitoneum, skin, and lymph nodes.
- Reasons for metastases remains unproven, but repeated surgical manipulation(s) may represent a primary factor in introducing neoplastic foci into vascular channels (iatrogenic implantation) resulting in metastatic disease; however, arguments against this postulation include:
 - Intravascular tumor foci not identified in reported cases of metastasizing pleomorphic adenoma
 - Vascular permeation in pleomorphic adenomas does not result in metastasis.

Pathology

Fine-Needle Aspiration Biopsy

- Identical to the aspiration of a nonmetastasizing pleomorphic adenoma (see previous):
 - Metastatic lesions contained benign epithelial, myoepithelial, and stromal components.
- Cells may be slightly atypical but the cytologic findings are not those of a carcinoma.

Gross

- Primary tumors are conventional pleomorphic adenoma including well-circumscribed to encapsulated solitary mass.
- Recurrent tumors may be a single mass or, as often occurs in recurrent pleomorphic adenomas, may be multinodular.
- Metastatic tumors may be a single mass lesion or multiple lesions and often appear well circumscribed or delineated and may even be encapsulated.
- Cut surface, particularly in recurrent tumor but also in primary or metastatic tumor, may show a prominently glistening appearance due to predominant chondromyxoid stroma.
- Tumor size, whether primary, recurrent, or metastatic tumor, ranges from less than 1 cm to as large as 15 cm.

Histology

- Identical to that of pleomorphic adenoma including admixture of epithelial, myoepithelial, and chondromyxoid stroma:
 - In any given tumor any of these histologic components may predominate such that the histologic spectrum includes:
 - Epithelial predominant
 - Myoepithelial predominant
 - Stromal predominant
- Metastatic foci histologically similar to primary and/or recurrent tumor(s)
- All tumor foci whether primary, recurrent, or metastasis lack evidence of malignancy, including an

absence of anaplasia, increased mitotic activity with atypical mitoses, necrosis, invasive growth; the presence of these features would exclude the diagnosis of metastasizing pleomorphic adenoma:

- Rare examples reported of carcinoma developing in:
 - Primary pleomorphic adenoma at some point subsequent to metastases
 - Metastatic pleomorphic adenoma
- Immunohistochemistry:
 - Primary and metastatic foci share similar immunostaining as nonmetastasizing pleomorphic adenoma (see previous discussion on [pleomorphic adenoma](#)).
- Cytogenetics and molecular genetics:
 - No difference in DNA ploidy analysis between primary, recurrent, or metastatic tumors
 - FISH analysis in a small number of cases has identified the presence of two related hypodiploid clones in skeletal metastases that differ from cytogenetic profile of “conventional” pleomorphic adenoma, suggesting presence of tumor suppressor genes in metastasizing pleomorphic adenoma.

Differential Diagnosis

- Other categories of malignant mixed tumors
- In osseous and less so in nonosseous locations, diagnostic considerations may include primary chondroid and chondroid-related tumors, including chondrosarcoma and chordoma.
- Chondroid hamartoma of the lung:
 - Cartilaginous nests surrounded by cellular fibrous tissue and presence of adjacent alveoli and bronchioles assist in identifying chondroid hamartoma.

Treatment and Prognosis

- Preferred treatment is complete surgical excision of all tumor foci (primary, recurrent, metastases).
- Adjunct radiotherapy has been used, but its efficacy in treatment of metastatic tumor is questionable.
- High recurrence rate with approximately 90% of patients experiencing one or more recurrence of their pleomorphic adenoma at primary site of occurrence
- Prognosis is generally good even with metastatic disease; however, death may occur from metastatic disease:
 - Mortality rates range from 20% to 37%.
 - Death reported from as early as 6 months after discovery of metastasis to years later
 - More aggressive clinical course reported in immunocompromised patients (e.g., cardiac transplantation)

BASAL CELL ADENOCARCINOMA

(Figs. 20-99 and 20-100)

Definition: Low-grade malignant epithelial salivary glands neoplasm with features of basal cell adenoma but with infiltrative growth and potential for metastatic disease

- Considered malignant counterpart of basal cell adenoma.

Synonyms: Malignant basal cell adenoma; basal cell carcinoma; basaloid salivary carcinoma; carcinoma ex monomorphous adenoma

Clinical

- Uncommon salivary gland neoplasm
- No gender predilection; occurs over a wide age range but most frequently seen in fourth to ninth decades of life; rarely occurs in children
- Most commonly occurs in parotid gland (superficial lobe):
 - Approximately 90% occur in parotid gland
 - Less common sites of occurrence include submandibular gland and minor salivary glands.
- Symptoms relate to mass with or without associated pain or tenderness; duration of symptoms may be from months to years.

Fig. 20-99. Basal cell adenocarcinoma of the parotid gland.

A, At low magnification the tumor is unencapsulated, infiltrative into the parotid parenchyma (*top*), and composed of solid and trabecular growth. **B,** Higher magnification shows tumor nests infiltrating parotid parenchyma. **C,** Basaloid cell proliferation composed of pleomorphic nuclei and increased mitotic activity. **D,** Perineural and perivascular invasion. The cytologic atypia contrast to basal cell adenoma, which typically are composed of cytologically bland-appearing nuclei. In some examples of basal cell adenocarcinoma there may be an absence of cytologic atypia (see next illustration).

Fig. 20-100. Basal cell adenocarcinoma of minor salivary glands.

A, Submucosal infiltrative tumor characterized by trabecular and lobular growth; note the intact surface epithelium to the extreme left. **B**, Neoplastic cells include admixture of smaller cells with hyperchromatic nuclei and larger cells with vesicular nuclei; note the bland-appearing cells lacking significant nuclear pleomorphism and mitotic activity. **C**, Solid area composed of uniform basaloid-appearing cells. The cytomorphic features seen in **B** and **C** could be those of a basal cell adenoma. However, in contrast to basal cell adenoma, there is infiltrative growth in basal cell adenocarcinoma, including (**D**) peri- and intraneural invasion (*arrow*) and lymphovascular invasion (*arrowhead*). Although not illustrated here invasion of salivary gland parenchyma would also support a diagnosis of basal cell adenocarcinoma rather than basal cell adenoma in those cases with shared bland cytomorphic findings.

- Most arise de novo but may occur in association with or develop from a basal cell adenoma:
 - Most often membranous type of basal cell adenoma
 - Reported to occur in 23% of cases
- Concomitant dermal eccrine cylindroma may be identified, suggesting a salivary gland-skin adnexal diathesis.
- Suggestion that basal cell adenocarcinoma represents the solid variant of adenoid cystic carcinoma, but differences in histology and biology support separate classification.

- In infants presence of hybrid basal cell adenoma and adenoid cystic carcinoma represents sialoblastoma (see [Sialoblastoma](#)).

Pathology

Gross

- Circumscribed but unencapsulated, solid, tan-white mass varying in size from 0.7 to 4 cm in diameter; cystic foci may be focally identified.

Fine-Needle Aspiration Biopsy

- Aspiration findings are essentially identical to those of basal cell adenoma (see previous).

- Histology of many basal cell adenocarcinomas is similar to basal cell adenoma but features of malignancy may be present and identifiable by FNAB, including:
 - Marked nuclear pleomorphism with increased nuclear-to-cytoplasmic ratio
 - Increased mitotic activity
 - Necrosis

Histology

- Morphologic similarity to basal cell adenoma including:
 - Variably sized nodules or islands of tumor cells growing in solid, trabecular, membranous, and/or tubular patterns
 - Variety of morphologic patterns can be seen in any given neoplasm.
 - Solid growth with tumor nests separated by eosinophilic basal lamina (i.e., membranous pattern) or trabecular pattern is most frequent
- Lesional cells composed of uniform, basaloid epithelial cells consisting of two cell types:
 - Large round to polygonal to elongated cell with pale staining basophilic nuclei, eosinophilic to amphophilic cytoplasm, and indistinct cell borders
 - Small, round cell with dark (basophilic) nuclei, scant cytoplasm and indistinct cell borders:
 - Tend to be located peripheral to the larger cells
 - Peripheral palisading of nuclei may be seen but tends to be less prominent as compared with basal cell adenoma.
 - Of the two cellular components larger cells tend to be more common, although in any given tumor they may be seen in equal proportion.
 - Overall cytomorphology may be predominantly bland, lacking significant nuclear pleomorphism, increased mitotic activity, or necrosis.
 - Nuclear pleomorphism, increased mitotic activity, and necrosis may be seen but not consistently identified or diagnostic for carcinoma.
- Eosinophilic, hyalinized, PAS-positive basal lamina can be seen either as intercellular droplets or perinodule membranes.
- Additional findings may include presence of:
 - Tubular structures may focally be present.
 - Squamous differentiation:
 - Identified in approximately 25% of cases
 - Spindle-shaped cells
 - Cystic or cribriform patterns may be present.
- A stromal benign lymphoplasmacytic cell infiltrate may be present.
- Histologic hallmark for diagnosis of basal cell adenocarcinoma rests on the identification of infiltration as manifested by:
 - Invasion of adjacent structures (e.g., salivary gland parenchyma, soft tissue structures)
 - Lymph-vascular invasion
 - Neurotropism (e.g., perineural or intraneural invasion)
- Histochemistry:
 - In general, PAS- and mucicarmine-positive material is absent or minimally present within the basal cell adenocarcinoma; PAS-positive material may be seen within tubular lumens.
- Immunohistochemistry:
 - Consistent and diffuse pan-cytokeratin (AE1/AE3) positive
 - Most are reactive for CK14 with variable reactivity for CK7, 8, 18, 19
 - Vimentin positive
 - Focal reactivity for S100 protein, smooth muscle actin (usually peripherally located cells), carcinoembryonic antigen, epithelial membrane antigen
 - c-kit (CD117) immunoreactivity reported
 - Low proliferation rate (<5%) as seen by Ki67 staining
- Electron microscopy:
 - Similar to basal cell adenoma with evidence of differentiation along basal, myoepithelial, and ductal cell lines:
 - Basal cells: rough endoplasmic reticulum, mitochondria, tonofilaments, and desmosomes
 - Myoepithelial cells: cytoplasmic myofilaments, plasmalemmal extensions, and desmosomes
 - Ductal cells: microvilli, tight junctions, and desmosomes
- Cytogenetics and molecular genetics:
 - Chromosomal gains and losses, including:
 - Gains: 9p21.1-pter, 18q21.1-q22.3, 22q11.23-q13.31
 - Losses: 2q24.2, 4q25-q27
 - Loss of heterozygosity with high frequency at 16q12-13 regions:
 - Seen in sporadic cases and in cases of familial basaloid tumors and dermal cylindroma cases
 - Absence of *MYB-NFIB* fusion transcript
- Hybrid tumor:
 - May occur as part of a hybrid salivary gland tumor in association with other salivary gland tumors (e.g., adenoid cystic carcinoma)

Differential Diagnosis

- Basal cell adenoma:
 - Presence of invasive growth distinguishes basal cell adenocarcinoma from basal cell adenoma
- Cellular pleomorphic adenoma
- Adenoid cystic carcinoma:
 - In contrast to basal cell adenocarcinoma, adenoid cystic carcinomas:

- Have prominent cribriform pattern of growth with pseudocyst formation (features usually not present in basal cell adenocarcinoma)
- Lack dual cell population (mixture of small and large cells seen in basal cell adenocarcinoma)
- Lack peripheral nuclear palisading
- Lack squamous differentiation
- Presence of *MYB-NFIB* fusion transcript
- Myoepithelial carcinoma
- Basaloid squamous cell carcinoma
- Adamantinoma-like Ewing sarcoma (AES):
 - Rare variant of the Ewing family of tumors that resembles classic adamantinoma of bone
 - AES shows epithelial differentiation and complex immunohistochemical expression profile with keratin and basal marker immunoreactivity and can resemble a variety of carcinomas.
 - May rarely occur in parotid gland histologically simulating basal cell adenocarcinoma including:
 - Nested basaloid proliferation with peripheral palisading in tumor nests
 - “Basaloid” epithelial differentiation by cytokeratin (AE1/AE3) and p40 positivity
 - Unlike most basal cell adenocarcinomas, AES demonstrate:
 - High grade morphology
 - Absence of true ductal or myoepithelial component
 - Tendency toward neuroectodermal phenotype with focal rosette formation, CD99, and weak synaptophysin immunoreactivity
 - Presence of EWSR1 and FLI1 fluorescence in situ hybridization confirms presence of translocation supporting diagnosis.

Treatment and Prognosis

- Complete surgical excision is the preferred treatment:
 - For parotid gland, superficial parotidectomy
 - For submandibular gland, complete glandectomy
 - For minor salivary gland, wide excision to include tumor-free margins
- Unless lymph node involvement is clinically evident, neck dissection would not appear warranted.
- Local recurrences frequent especially for tumors of minor salivary glands:
 - 71% for minor salivary gland tumors
 - 37% for major salivary gland tumors
- Metastatic disease is uncommon:
 - Occurs in 21% of minor salivary gland cases
 - Occurs in 11% of minor salivary gland cases
 - Involves regional lymph nodes and rarely lungs
- Prognosis is generally excellent:
 - Death due to disease is uncommon.

EPITHELIAL-MYOEPITHELIAL CARCINOMA (EMC)

(Figs. 20-101 through 20-105)

Definition: Low-grade malignant epithelial salivary gland neoplasm characterized by presence of ductal structures composed of two cell types, including inner (luminal) epithelial cells and outer (abluminal) myoepithelial cells.

Synonyms: Clear cell adenoma/carcinoma; glycogen-rich clear cell adenoma/carcinoma; clear cell carcinoma; tubular carcinoma; adenomyoepithelioma

Clinical

- Uncommon salivary gland neoplasm
- Slightly more common in women than in men; may occur over a wide age range but is most frequently encountered in the sixth to seventh decades of life
- Approximately 75% to 80% occur in parotid gland:
 - Other sites of involvement include submandibular gland and minor salivary glands throughout the upper aerodigestive tract including:
 - Oral cavity (palate)
 - Sinonasal tract
- Symptoms usually relate to asymptomatic, slow-growing mass:
 - Associated pain and/or facial nerve paralysis occur infrequently
 - Ulceration of a mucosal-based lesion may be present
 - Duration of symptoms ranges from months to years

Pathology

Gross

- Well-circumscribed but unencapsulated, solid, firm, tan-white to yellow mass measuring from 1 to 12 cm in greatest dimension
- Hemorrhage and necrosis may occasionally be identified.
- Minor salivary gland involvement may be associated with mucosal ulceration.

Fine-Needle Aspiration Biopsy

- Smears generally cellular with no specific architectural pattern
- Biphasic pattern including epithelial (small cell) and myoepithelial (large/clear cell) may be identified:
 - Epithelial cells are small.
 - Myoepithelial cells are large with abundant clear cytoplasm, distinct cell borders, and uniform, small nuclei.
 - Biphasic pattern may be subtle or absent since the clear cells have a fragile cytoplasm and often appear as naked nuclei.

Fig. 20-101. Epithelial-myoepithelial carcinoma.

Epithelial-myoepithelial carcinoma of the parotid gland. **A**, Unencapsulated tumor invading into the parotid gland parenchyma (*lower left*). **B**, Characteristic tubular growth composed of a dual cell population with luminal or inner epithelial cell layer appearing as dark staining cuboidal to columnar cells with central or basally placed nuclei and eosinophilic cytoplasm and outer abluminal or outer myoepithelial cell layer appearing as polyhedral-shaped cells with eccentrically placed nuclei, abundant clear cytoplasm, and distinct cell borders; **C** through **E**, cytokeratin (CAM5.2) shows dedicated reactivity of the luminal cells while dedicated staining of the outer myoepithelial cells by **(D)** p63 (nuclear) and **(E)** S100 protein (nuclear and cytoplasmic).

Fig. 20-102. Epithelial-myoepithelial carcinoma.

Often these tumors are infiltrative including neurotropism (*left*) and invasion into adipose tissue (*right*).

- Single cells and naked nuclei were prominent in all cases.
- Globules of hyalinized basal lamina may occasionally be seen.

Histology

- Circumscribed but unencapsulated tumors:
 - Often multinodular or multilobulated
- Infiltration present and includes invasion into adjacent/surrounding salivary gland parenchyma, neurotropism, perivascular invasion, angioinvasion, and osseous invasion.
- Tumor nests frequently have an organoid arrangement but may also have a cystic, papillary, and/or solid growth.
- Histologic hallmark is presence of two cell types identified in varying proportions in any given tumor:
 - Luminal or inner epithelial cell layer:
 - Dark staining cuboidal to columnar cells with central or basally placed nuclei and scant eosinophilic cytoplasm

Fig. 20-103. Epithelial-myoepithelial carcinoma.

Variant growth patterns and cell types may include (A) solid and trabecular; (B) cribriform; (C) small tubules; (D) cordlike; (E) solid; and (F) fascicular composed of spindle-shaped cells. In some of these examples there is overgrowth of the myoepithelial cell component obscuring the epithelial cell component.

Fig. 20-104. Epithelial-myoepithelial carcinoma.

Additional variant findings in epithelial-myoepithelial carcinoma may include (A) tumors with myoepithelial cell overgrowth predominated by cells with clear cytoplasm with limited but identifiable epithelial component characterized by tubular growth composed of luminal cells with eosinophilic cytoplasm; (B) double clear cell variant in which both luminal and abluminal cells are composed of cells with clear cytoplasm.

- Surround small lumens, which may appear cystic and contain eosinophilic proteinaceous material
- Abluminal or outer myoepithelial cell layer:
 - Polygonal cells with eccentrically placed nuclei, abundant clear cytoplasm, and distinct cell borders
 - Variant myoepithelial morphologies may include:
 - Predominance of myoepithelial cells especially in tumors with solid growth that may obscure epithelial cell layer: referred to as *EMC with myoepithelial overgrowth*;

Fig. 20-105. Epithelial-myoepithelial carcinoma.

Prominent hyalinization may be present.

- “Verocay”-like nuclear palisading may be identified
 - Spindle shaped or elongated
- Lesional cells show mild to moderate pleomorphism but marked cytomorphic atypia not typically seen:
 - Mitotic activity is absent to low (2 mitoses or fewer per 10 high-power fields)
 - Necrosis usually absent but may be present within the center of tumor lobules
 - “Ancient” changes in form of focal marked nuclear pleomorphism (similar to “monster” cells in pleomorphic adenomas) may be present
- Tumor nests variably separated by thin fibrovascular stroma to loose myxoid stroma to basement membrane-like material that may be thickened appearing as eosinophilic, hyalinized membrane that is PAS positive.
- Histologic variants include:
 - Oncocytic variant
 - Uncommon variant constitute up to 8% of all EMCs
 - Oncocytic EMC:
 - Occurs in patients decades older than conventional EMC
 - Often papillary with calcification and associated sebaceous components
 - Apocrine variant
 - Named for its apocrine ductal component
 - May be mistaken for salivary duct carcinoma.
 - Epithelial component often shows overgrowth in a cribriform or even solid pattern.
 - Immunophenotypically defined by androgen receptor and gross cystic disease fluid protein

- 15 positivity. The most important aspect of differentiating oncocytic and apocrine EMC from other salivary oncocytic tumors is recognition of the biphasic nature of these variants and confirmation that the abluminal outer layer consists of plump, “activated” myoepithelial cells, regardless of tinctorial characteristics.
- Oncocytic and apocrine variants have indolent biology.
 - Double clear cell variant:
 - Luminal and abluminal cells composed of cells with clear cytoplasm
 - Usually predominated by clear-appearing epithelial cells often columnar and stratified containing large-caliber tubules
 - Surrounding myoepithelial cells also typically clear appearing
 - Sebaceous variant:
 - Rare occurrence
 - Histologically show areas of sebaceous differentiation admixed with features of bilayered ductal structures typical of EMC
 - Sebaceous differentiation may be diffusely or focally identified.
 - Generally lack cytologic atypia
 - Positive immunoreactivity for EMA confirmed sebaceous differentiation
 - Low-grade malignancy similar to conventional EMC
 - EMC ex pleomorphic adenoma
 - May be malignant component in carcinoma ex pleomorphic adenoma (EMC ex pleomorphic adenoma)
 - EMC with myoepithelial anaplasia
 - Represents progression to histologically higher-grade EMC
 - Characterized by solid growth, increased nuclear atypia in more than 20% of myoepithelial cells, and increased mitotic activity
 - Transition to severe nuclear atypia in myoepithelial cells gradual rather than abrupt with intervening areas of moderate nuclear atypia
 - Anaplastic component may include transition to squamous cell carcinoma.
 - Associated with worse prognosis
 - Histochemistry:
 - Luminal or inner epithelial cells:
 - May show diastase-resistant, PAS-positive intracytoplasmic material
 - Mucicarmine negative
 - Luminal eosinophilic material is PAS positive and mucicarmine negative
 - Abluminal or outer (myoepithelial) cells:
 - May show diastase-sensitive, PAS-positive intracytoplasmic material
 - Mucicarmine negative but rarely may be positive
 - Immunohistochemistry:
 - Luminal or inner epithelial cells:
 - Cytokeratins and EMA:
 - Strongly positive
 - Dedicated CAM5.2 staining
 - S100 protein and SOX10 variably immunoreactive
 - Absence of myoepithelial markers
 - Abluminal or outer (myoepithelial) cells:
 - p63, S100 protein, calponin, smooth muscle actin, smooth muscle myosin heavy chain, muscle-specific actin and SOX10 positive
 - Cytokeratin and EMA variably and often weakly reactive:
 - Absence of CAM5.2
 - GFAP occasionally reactive
 - Low proliferation rate (<5%) as seen by Ki67 staining
 - bcl-2 and c-kit frequently positive
 - DOG1 may be positive, showing combined apical ductal and membranous/cytoplasmic myoepithelial staining profile
 - Renal cell carcinoma marker, CD10, PAX2, PAX8, and CAIX negative
 - Electron microscopy:
 - Luminal or inner epithelial cells:
 - Lumina, microvilli, junctional complexes, desmosomes
 - Golgi complexes, dilated endoplasmic reticulum, dense core secretory granules, tonofilaments
 - Abluminal or outer (myoepithelial) cells:
 - Intracytoplasmic microfilaments with focal densities, subplasmalemmal plaques, and multilayered basal lamina
 - Fewer organelles as compared with epithelial cells
 - Cytogenetics and molecular genetics:
 - To date, no translocation has been identified but a limited number of cases evaluated found *HRAS* exon 3, codon 61 mutation.
 - Classic (low-grade) EMC lack *MYB* translocation
 - Hybrid tumor:
 - May occur as part of a hybrid salivary gland tumor in association with other salivary gland tumors (e.g., adenoid cystic carcinoma [AdCC], salivary duct carcinoma, others)
 - Hybrid EMC-AdCC may harbor *MYB* translocation.
 - High-grade transformation (“dedifferentiation”) of EMC:
 - Rare occurrence
 - Transition from foci of EMC to histologic high-grade carcinoma characterized by nuclear

- pleomorphism, increased mitotic activity, and necrosis
- Ki67 labeling index significantly increased in high-grade carcinoma component as compared with foci of EMC
- Associated with worse prognosis
- May harbor *MYB* translocation suggesting close relationship (or possibly a variant) to adenoid cystic carcinoma

Differential Diagnosis (Table 20-10)

- Clear cell oncocytoma
- Clear cell myoepithelioma
- Mucoepidermoid carcinoma, clear cell variant
- Acinic cell adenocarcinoma, clear cell variant
- Primary salivary gland clear cell carcinoma
- Metastatic tumors composed of clear cells, a rare phenomenon, including:
 - Renal cell carcinoma:
 - Absence of biphasic cell pattern, prominent fibrovascular stroma, and presence of CD10, renal cell carcinoma marker, PAX2, PAX8, and CAIX immunoreactivity
 - Thyroid carcinoma:
 - Absence of biphasic cell pattern and presence of thyroglobulin and thyroid transcription factor 1 (TTF-1) immunoreactivity

Treatment and Prognosis

- Complete surgical excision is preferred treatment.
- Adjunctive radiotherapy used in cases in patients whose tumors cannot be completely excised or when there is doubt as to the completeness of surgical resection
- Local recurrence is frequent occurrence seen in 30% to 50% of patients:
 - Most recurrences within 5 years of the initial resection but may also occur many years or decades after initial surgery
 - Multiple recurrences may occur

TABLE 20-10 Salivary Gland Tumors with Clear Cells: Differential Diagnosis

Tumor	Histology	Histochemistry	IHC	Cytogenetics
EMC	Dual cell population: (1) luminal or inner epithelial cell layer composed of dark staining cuboidal to columnar cells with eosinophilic cytoplasm surrounding small lumens and (2) abluminal or outer myoepithelial cell layer polyhedral cells with eccentrically placed nuclei, abundant clear cytoplasm and distinct cell borders	Epithelial cells: diastase-resistant, PAS-positive intracytoplasmic material, mucicarmine negative. Myoepithelial (clear) cells: diastase-sensitive, PAS-positive intracytoplasmic material; mucicarmine negative. Intraluminal eosinophilic material: PAS-positive and mucicarmine negative	Epithelial cells: cytokeratin (AE1/AE3, CAM5.2) and EMA positive. Myoepithelial cells: S100 protein, p63, calponin, SMA positive	Limited number of cases positive for <i>HRAS</i> exons 3, codon 61 mutations
CCC (hyalinizing and non-hyalinizing)	Dominated by cells with clear cytoplasm; cells with slightly eosinophilic appearing cytoplasm may be seen scattered throughout the tumor; stromal hyalinization may or may not be present	Diastase-sensitive, PAS-positive; mucicarmine negative	Cytokeratin and EMA positive; limited to absent reactivity for myoepithelial cell markers including S100 protein, p63, calponin, SMA	<i>EWSR1-ATF1</i> (hyalinizing CCC)
MEC, clear cell type	Pure clear cell variant of MEC likely nonexistent; clear cells are round to oval cells with clear cytoplasm, distinct cell borders, peripherally-placed, small, dark nuclei; clear cells may be seen and infrequently may predominate but areas of residual MEC including admixture of mucocytes, epidermoid cells and intermediate cells present	Diastase-resistant, PAS-positive; mucicarmine positive	Cytokeratin positive; p63 positive but other myoepithelial cell markers negative, including S100 protein, calponin, SMA	<i>CRTC1-MAML2</i>

Continued

TABLE 20-10 Salivary Gland Tumors with Clear Cells: Differential Diagnosis—cont'd

Tumor	Histology	Histochemistry	IHC	Cytogenetics
ACC, clear cell type	Clear cells round to oval, distinct cell borders, small peripherally placed dark nuclei; clear cells result from fixation and/or tissue processing; “pure” clear cell variant likely does not exist	Diastase-resistant, PAS-positive; mucicarmine negative	Cytokeratin, DOG1 positive; myoepithelial cell markers negative, including S100 protein, p63, calponin, SMA	None known
Oncocytoma, clear cell type	Partial or complete replacement of granular eosinophilic cytoplasm by cells with clear, nongranular-appearing cytoplasm; transition areas of typical oncocytes to clear cells may be present; other than the cytoplasmic appearance, the histology and histochemical staining is similar to the more conventional type of oncocytoma; clear cytoplasm is due in part to fixation and tissue processing artifact, and to accumulation of glycogen within the cytoplasm displacing the mitochondria to the periphery of the cells	Diastase-sensitive, PAS-positive granules; oncocytes show intracytoplasmic blue-black granules by PTAH staining	Cytokeratin, EMA positive; myoepithelial cell markers negative, including S100 protein, p63, calponin, SMA	None known
Myoepithelioma and myoepithelial carcinoma, clear cell type	Clear cells have defined cell membranes; one cell type among several different cell types seen in myoepithelioma with transition areas of typical myoepithelial cells to clear cells present	Clear cells are diastase-sensitive, PAS-positive; mucicarmine negative	Cytokeratins, EMA, p63, calponin, S100 protein, SMA, vimentin positive	<i>EWSR1-ATF1</i> reported in clear cell type of myoepithelial carcinoma
RCC	Cell nests separated by thin fibrovascular cores; clear cells have sharp cell membranes; red cells characteristically seen within luminal spaces	Clear cells are diastase-sensitive, PAS-positive; mucicarmine negative	Cytokeratins (AE1/AE3, CAM5.2), EMA, CD10, renal cell marker, PAX2, PAX8, CAIX, vimentin positive; HMWCK, CK7 and CK20 negative; myoepithelial cell markers, GATA3 negative	Partial or complete chromosome 3 loss or mutation on short arm chromosome 3p; alterations in chromosomes 14, 8, and 9
TC, papillary or follicular types	Metastasis from thyroid in general is rare and one entirely comprised of clear cells unlikely; in this scenario clear cells represent part of metastatic cellular composition that includes follicular epithelial cells with or without identifiable colloid, and with or without nuclear features of thyroid papillary carcinoma; clear cells have abundant clear to slightly granular appearance	Clear cells are typically PAS and mucicarmine negative; colloid is diastase-resistant, PAS-positive	Cytokeratins, thyroglobulin, TTF1, positive; myoepithelial cell markers negative	<i>RET/PTC</i> and <i>BRAF</i> mutations for more usual types of papillary carcinomas; <i>RAS</i> mutation for follicular variant papillary thyroid carcinoma, follicular adenoma, follicular carcinoma

ACA, Acinic cell adenocarcinoma; CAIX, carbonic anhydrase 9; CCC, clear cell carcinoma (nonhyalinizing and hyalinizing); EMA, epithelial membrane antigen; EMC, epithelial myoepithelial carcinoma; MEC, mucoepidermoid carcinoma; PAS, periodic acid Schiff; PTAH, phosphotungstic acid hematoxylin; RCC, renal cell carcinoma; TC, thyroid carcinoma; SMA, smooth muscle actin; TTF1, thyroid transcription factor 1.

- Metastatic tumor:
 - Metastases occur most often to regional (cervical and periparotid) lymph nodes:
 - Reported in up to 20% of cases
 - Less common, distant metastases occur primarily to lungs, kidney, and brain:
 - Reported in less than 10% of cases
 - Metastases may occur 10 years or more after the initial resection.
- In general, the prognosis is excellent:
 - 5-year survival rate reported to be 80%
 - 10-year survival rate reported to be 72%
 - Death may occur restricted to but not always seen in cases with metastatic tumor
- Factors associated with adverse prognosis include:
 - Large tumor size
 - Rapid growth
 - Occurrence in minor salivary glands (likely related to incomplete surgical resection)
 - Solid growth pattern
 - Nuclear atypia in greater than 20% of the tumor
 - DNA aneuploidy
 - High proliferative activity
- Factors affecting disease-free survival include:
 - Positive margin status
 - Presence of angiolymphatic invasion
 - Presence of necrosis
 - Presence of myoepithelial anaplasia
- Connection to surface mucosa in many cases
- Presence of consistent diffuse p63 immunoreactivity
- Ultrastructural presence of tonofilaments, well-formed desmosomes, and hemidesmosomes
- Presence of squamous and mucinous differentiation may indicate HCCC is a low-grade sclerosing adenosquamous carcinoma
- Other evidence show similarities to clear cell odontogenic carcinoma (CCOC) except by location including similar:
 - Histology
 - *EWSR1-ATF1* rearrangements (a finding not present in other clear cell neoplasms in the differential diagnosis)

• Until more clearly defined as being separate from CCC, both types of clear cell neoplasms are included under a single category with the possibility that future classification may separate these two entities.

Clinical

- Uncommon tumor
- No gender predilection; primarily identified in the fifth through eighth decades of life; rare in children
- Most frequently occur in intraoral sites:
 - Palate and base of tongue most common sites of occurrence
 - Other intraoral sites include buccal mucosa, floor of mouth, tongue, lip, retromolar area, and tonsillar region
 - Other less common sites of occurrence include:
 - Major salivary glands: parotid gland \gg submandibular gland
 - Nasopharynx, hypopharynx, larynx, lacrimal gland
- Most commonly present as an asymptomatic swelling
 - Pain and mucosal ulceration may be present; osseous invasion and fixation to surrounding tissues may occur.

Pathology

Gross

- Poorly circumscribed, solid mass with a gray-white appearance usually measuring 3 cm or less in greatest dimension
- Prominent hyalinization may be grossly appreciated, imparting a scar-like/fibrotic appearance.
- Infiltration of adjacent tissues may be identified.

Fine-Needle Aspiration Biopsy

- Aspirates contain numerous groups and sheets of cohesive small and large epithelial cells:
 - Groups and sheets, which had sharp outlines and showed focal nuclear overlapping

CLEAR CELL CARCINOMA (CCC) AND HYALINIZING VARIANT (HCCC)

(Figs. 20-106 through 20-108)

Definition: Malignant epithelial salivary gland tumor composed exclusively of monomorphic population of cells characterized by their clear-appearing cytoplasm (with or without stromal hyalinization) without evidence of myoepithelial differentiation and lacking histomorphologic features of other salivary gland neoplasms that may be dominated by a prominent population of clear cells (e.g., mucoepidermoid carcinoma, acinic cell adenocarcinoma, epithelial-myoepithelial carcinoma, myoepithelial carcinoma, others).

Synonyms: Clear cell adenocarcinoma; hyalinizing clear cell adenocarcinoma; glycogen-rich clear cell carcinoma

Classification

- Evidence suggests that HCCC may represent a squamous mucosal-derived neoplasm rather than a neoplasm of seromucous gland origin; such evidence includes:

Fig. 20-106. Clear cell carcinoma of minor (oral cavity) salivary glands.

A, Submucosal unencapsulated and infiltrative tumor with trabecular solid, nested growth; the tumor is infiltrative into seromucous glands (*lower right*). **B**, Another example characterized by diffuse proliferation of cells exclusively composed of cells with clear cytoplasm. **C**, At higher magnification the entire neoplasm is comprised of cells with clear-appearing cytoplasm, distinct cell membranes, and rather bland-appearing nuclei lacking significant nuclear pleomorphism and increased mitotic activity. **D**, The lesional cells are p63 negative.

- Cells have uniform, round to ovoid nuclei, granular-appearing chromatin, small nucleoli, and abundant, well-defined clear-appearing cytoplasm.
- Myoepithelial cells or hyaline globules are absent.

Histology

- Clear cell carcinoma (CCC)
 - Unencapsulated infiltrative submucosal neoplasm with solid sheets, nests, cords, trabeculae, and single-cell growth patterns:
 - Ducts and gland-like spaces typically not identified
 - But may focally be seen although such structures may represent entrapped non-neoplastic ducts
 - Lesional cells may extend and involve overlying surface (squamous) epithelium.
- Lesional cells characterized by presence of abundant clear-appearing cytoplasm:
 - May predominate in any given lesion
 - Cells with slightly eosinophilic-appearing cytoplasm may be admixed with clear-appearing cells.
 - Nuclei are oval to round with finely granular-appearing chromatin, centrally to eccentrically located and inconspicuous to small nucleoli.
 - Cell borders/membranes are distinct.
- Cytomorphologically, cells are uniform in appearance with mild nuclear pleomorphism, although moderate pleomorphism may be present, scarce to absent mitotic figures; necrosis is not usually identified.
- Stromal findings include minimal collagen deposition, appearing as interconnecting fibrous septa.

Fig. 20-107. Hyalinizing clear cell carcinoma of minor (oral cavity) salivary glands.

A, The tumor is characterized by the presence of markedly thickened bands of sclerotic or hyalinized collagen in which nests and cords of lesional cells are seen. **B**, In contrast to clear cell carcinoma without hyalinization, which is exclusively composed of clear cells, in this tumor there is an admixture of cells with pale eosinophilic cytoplasm with clear cells rather than exclusively composed of clear-appearing cells. **C**, However, a predominance of clear cells may be seen in a minority of cases. Irrespective of the nature of the cytoplasm the cells are rather uniform with round to oval nuclei lacking significant pleomorphism and distinct cell membranes. **D**, The lesional cells are diffusely p63 immunoreactive.

- Histochemistry:
 - Intracytoplasmic diastase-sensitive, PAS-positive material indicative of glycogen
 - Mucicarmine staining usually negative
- Immunohistochemistry
 - Cytokeratins including high molecular weight focally to diffusely positive
 - CEA positive
 - Myoepithelial markers typically negative including S100 protein, p63, actins, calponin, and GFAP
 - Renal cell carcinoma (RCC) antibody, CD10, PAX2, PAX8, and CAIX negative
- Electron microscopy:
 - Features of duct cell differentiation including microvilli, tight junctions, desmosomes, tonofilaments, and basal lamina
 - Absence of myoepithelial differentiation
- Cytogenetics and molecular genetics:
 - No specific findings
- Hyalinizing clear cell carcinoma (HCCC)
 - Unencapsulated infiltrative submucosal neoplasm characterized by presence of markedly thickened bands of sclerotic or hyalinized collagen:
 - Hyalinized stroma may be intimately admixed with lesional cells, creating a somewhat

Fig. 20-108. Clear cell carcinoma of minor (oral cavity) salivary glands.

The tumor is infiltrative, including (A) invading into and through palatal bone and (B) perineural invasion, the latter confirmed by (C) S100 protein staining.

- cribriform arrangement that may simulate other more common salivary gland tumors
- In addition, a fibrocellular stroma that may appear myxoid (similar to pleomorphic adenoma) may be seen.
- Juxtaposition of two stroma types within the tumor essentially pathognomonic seen in most but not all cases
- Predominance of clear cells seen in a minority of cases:
 - Often cells with pale eosinophilic cytoplasm rather than clear cytoplasm are seen or there is an admixture of both cell types.
 - Nuclei are oval to round with finely granular-appearing chromatin, centrally to eccentrically located and inconspicuous to small nucleoli.
 - Cell borders/membranes are distinct.
 - “Raisinoid” or “popcorn”-appearing nuclear membrane irregularities may be seen.
 - Occasional pseudonuclear inclusions may be present.
- Cytomorphologically, cells are rather uniform in appearance with mild nuclear pleomorphism scarce to absent mitotic figures; necrosis is not usually identified.
- Cells are arranged in small nests, short and long cords, interconnecting thin trabecular structures, and single cells.
 - Tendency for cells in center of mass to be surrounded by or admixed with a hyalinized basement membrane-like material
 - Cells often sharply demarcated from desmoplastic or fibrocellular stroma
 - Cells at periphery have greater tendency for nest formation and for infiltration without stromal deposition or desmoplastic response.
 - May appear in short thin cords
 - Owing to absence of desmoplasia such cells at periphery may be difficult to appreciate by light microscopy
- Tumors often connect to surface mucosal epithelium either abruptly or as pagetoid-like growth of single cells and may be accompanied by pseudoepitheliomatous hyperplasia.
- Other findings may include:
 - Occasional presence of focal squamous differentiation
 - Occasional duct formation, which may be true ductal differentiation in the neoplasm or more likely represents entrapped ducts:
 - Particularly common in parotid gland cases and absent in oral cavity cases
- Histochemistry:
 - Intracytoplasmic diastase-sensitive, PAS-positive material indicative of glycogen

- Mucicarmine staining may show dot-like or frank intracytoplasmic positive material in a high proportion of cases.
- Congo red staining for amyloid is negative.
- Immunohistochemistry
 - Majority diffusely positive for pancytkeratin
 - In addition, most cases positive for high molecular weight cytokeratins, p63 (suggestive of squamous differentiation), and CK14
 - Many cases focally or diffusely positive for EMA, CK7, CK19, and CAM5.2
 - Negative for myoepithelial-related markers including S100 protein, actins, calponin, and GFAP
 - Renal cell carcinoma antibody, CD10, PAX2, PAX8, and CAIX negative
- Electron microscopy:
 - Shown to have tonofilaments, well-formed desmosomes, and hemidesmosomes:
 - These features suggestive of squamous differentiation
 - Additional findings include basal lamina.
- Cytogenetics and molecular genetics:
 - Consistent *EWSR1-ATF1* gene fusion:
 - Represents another lesion type associated with *EWSR1-ATF1* gene fusion (see Table 20-2)
 - This molecular signature not present in other clear cell neoplasms that may share features with HCCC; notable exception is clear cell odontogenic carcinoma
- Infiltration often present for CCC and HCCC including invasion:
 - Into (minor) salivary gland parenchyma
 - Neurotropism (perineural and intraneural)
 - Lymph-vascular invasion
 - Invasion into muscle and bone

Differential Diagnosis (Table 20-10)

- Clear cell oncocytoma
- Clear cell myoepithelioma
- Mucoepidermoid carcinoma, clear cell variant
- Acinic cell adenocarcinoma, clear cell variant
- Epithelial-myoepithelial carcinoma
- Clear cell odontogenic carcinoma:
 - Shown to have *EWSR1-ATF1* translocation supporting link with HCCC
- Squamous cell carcinoma with prominent clear cells (clear cell variant)
- Metastatic tumors composed of clear cells, a rare phenomenon including:
 - Renal cell carcinoma:
 - Presence of RCC antibody, CD10, PAX2, PAX8, and CAIX immunoreactivity

- Thyroid carcinoma:
 - Presence of thyroglobulin and thyroid transcription factor 1 (TTF-1) immunoreactivity

Treatment and Prognosis

- Complete surgical resection is preferred treatment.
- Considered to be a low-grade malignancy associated with a good prognosis following complete surgical excision
- Overall prognosis considered to be excellent:
 - Local recurrence may occur in up to 17% of cases.
 - May occasionally metastasize to regional lymph nodes or metastasize distantly (e.g., lungs):
 - Although usually very low rates of metastatic disease, nodal metastasis at presentation reported in 25% of cases
 - Death due to disease rarely may occur.
- Rare example of high-grade transformation of HCCC reported, raising the possibility that HCCC may represent yet another tumor type that can transform to a histologically higher grade neoplasm with potential for more aggressive biologic behavior

SALIVARY DUCT CARCINOMA (SDC)

(Figs. 20-109 through 20-112)

Definition: High-grade malignant epithelial salivary gland neoplasm arising from the excretory ducts histologically resembling ductal carcinoma of breast.

Synonym: Cribriform salivary gland carcinoma of excretory ducts

Clinical

- Represents less than 10% of all salivary gland malignancies
- More common in men than in women; most frequently identified in the sixth through eighth decades of life and tends to be uncommon in patients under the age of 50
- Parotid gland (related to Stensen duct) is most common site of occurrence:
 - Other sites of involvement may include:
 - Submandibular gland
 - Minor salivary glands, most often related to palate
 - Rare sites of involvement include sublingual gland, paranasal sinuses, larynx.
- Symptoms include a (parotid) mass often with associated rapid enlargement with or without pain or facial nerve paralysis:
 - At presentation, cervical lymphadenopathy may be present.

Fig. 20-109. Salivary duct carcinoma, fine-needle aspiration biopsy.

A, B, Aspirate of parotid gland lesion showing cohesive sheets of epithelial cells with hyperchromatic, pleomorphic round to oval nuclei, prominent nucleoli, and granular cytoplasm. Following resection the tumor proved to be a salivary duct carcinoma.

- Majority arise de novo but may also occur as malignant component in carcinoma ex pleomorphic adenoma:
 - Clinical scenario in the setting of a carcinoma ex pleomorphic adenoma is that of rapid enlargement of a long-standing salivary gland mass lesion.

Pathology

Gross

- Majority are poorly circumscribed and infiltrative but may occasionally appear circumscribed.
- Cut section reveals a tan-white to gray-yellow solid mass ranging in size from 1 to 10 cm in greatest dimension; on average these tumors measure 3.5 cm.
- Cystic spaces filled with necrotic material may be identified.

Fine-Needle Aspiration Biopsy

- Characteristic cytomorphologic features include presence of three-dimensional cohesive clusters and flat sheets of epithelial cells:
 - Cribriform and papillary pattern of growth
 - Tumor cells are large polygonal and spindle shaped.
 - Eccentrically located, hyperchromatic, pleomorphic round to oval nuclei with indistinct to prominent nucleoli
 - Abundant finely granular cytoplasm or vacuolated cytoplasm
 - Increased mitotic activity
 - Necrosis in the smear background

Histology

- Intraductal and infiltrating neoplasm with a variety of growth patterns including cell nests, nodules or lobules with central comedo-type necrosis, cribriform, solid, cystic, and papillary:
 - Multiple growth patterns can be seen in any given tumor.
 - Comedotype necrosis is a characteristic but not pathognomonic finding.
 - Larger nodules tend to be cystic and irregular in shape.
 - Appearance may suggest growth confined to within ducts (intraductal) but features of invasive growth include:
 - Absence of myoepithelial layer
 - Much larger size of cystic foci as compared with normal ducts (intralobular and interlobular)
 - Presence of stromal fibrosis
 - Absence of normal (non-neoplastic) salivary gland parenchyma within neoplastic foci
- Neoplastic cells are large, cuboidal to polygonal with round often centrally situated hyperchromatic nuclei, prominent eosinophilic nucleoli, and abundant eosinophilic cytoplasm; apocrine features including decapitation secretion are commonly present.
 - Moderate to marked nuclear pleomorphism present
 - Significant increase in mitotic activity that may include atypical mitoses
- Cribriform pattern reminiscent of intraductal mammary carcinoma and includes so-called Roman bridge pattern characterized by bands of neoplastic epithelium arched over luminal spaces:
 - This pattern contrasts with the cribriform pattern seen in adenoid cystic carcinoma, which lacks Roman bridge appearance.
 - In addition, adenoid cystic carcinoma demonstrates an admixture of abluminal cells lining

Fig. 20-110. Salivary duct carcinoma.

A and **B**, Infiltrative parotid gland tumor characterized by varied growth, including cystic, cribriform, and solid with foci of comedotype necrosis. **C** and **D**, The cytologic features include large cells with pleomorphic vesicular nuclei, eosinophilic nucleoli, and abundant eosinophilic cytoplasm; **C**, mitotic activity and **D**, apocrine features are commonly seen. **E**, Diffuse and strong nuclear staining for androgen receptor is a characteristic although not pathognomonic finding. **F**, Diffuse GATA-3 (nuclear) staining is another marker seen in salivary duct carcinoma.

Fig. 20-111. Salivary duct carcinoma.

Sarcomatoid variant of salivary duct carcinoma characterized by **(A)** fascicular to storiform growth and **(B)** spindle-shaped cells with marked nuclear pleomorphism and increased mitotic activity. There is an absence of identifiable ductal component. **C**, Focally a ductal component is seen in association with the malignant spindle-shaped cells. **D**, Diffuse cyokeratin immunoreactivity confirms the epithelial nature of the malignant spindle cells.

pseudocysts and scattered epithelial cells lining small duct-like spaces, a pattern not seen in salivary duct carcinoma.

- Papillary pattern includes projections of neoplastic epithelium with fibrovascular cores.
- Additional findings may include:
 - Apocrine-like apical globules (apocrine SDC)
 - Oncocytic cytoplasmic changes may be present.
 - Squamous differentiation/metaplasia in form of keratinization and intercellular bridges
 - Psammoma-like bodies may be present.
- Stromal changes include the presence of fibrosis, often dense or sclerotic, as well as a mixed lymphoplasmacytic cell infiltrate.
- Invasive growth includes angioinvasion, neural invasion, and invasion of adjacent salivary gland parenchyma and surrounding soft tissue structures, including adipose tissue, skeletal muscle, and overlying skin:
 - Often there is extraglandular extension.
- Histologic variants include:
 - SDC, sarcomatoid variant:
 - Characterized by SDC with associated malignant spindle-shaped and pleomorphic cell infiltrate
 - Sarcomatoid proliferation may predominate with only limited evidence of ductular component.
 - Heterologous elements such as osteosarcomatous foci may be present; similar findings can be seen in spindle cell squamous carcinoma and is not indicative of a carcinosarcoma

Fig. 20-112. Salivary duct carcinoma.

Other variants of salivary duct carcinoma include (**A** and **B**) micropapillary characterized by clusters of morula-like epithelial cells with fibrovascular cores; (**C** and **D**) mucin-rich characterized by presence of lakes of extracellular mucin within which are nests or islands of neoplastic epithelium.

- SDC, micropapillary variant:
 - Characterized by SDC with associated clusters of morula-like epithelial cells with fibrovascular cores
 - Reported to be more aggressive than “conventional” salivary duct carcinoma
- SDC, mucin-rich variant:
 - Characterized by conventional SDC with associated lakes of extracellular mucin within which are nests or islands of neoplastic epithelium
- SDC, oncocytic variant:
 - Characterized by conventional SDC with oncocytic cells, the latter showing abundant eosinophilic cytoplasm
 - At least 50% of the neoplasm should be composed of oncocytic cells to invoke a diagnosis of this variant.
- SDC, osteoclast-like giant cell variant:
 - Characterized by conventional SDC with associated osteoclast-like giant cells, latter resembling cells seen in giant cell tumor of bone
 - In contrast to cells in a giant cell tumor, osteoclast-like giant cells in SDC are immunoreactive for epithelial markers and androgen receptor.
- High-grade SDC in situ (SDCIS)
 - Rare variant that may occur in major and minor glands
 - Characterized by intraductal proliferation of high-grade malignant cells similar to ductal carcinoma in situ of the breast:
 - Variable degrees of nuclear pleomorphism, prominent central nucleoli, eosinophilic to vacuolated cytoplasm, some with apocrine snouts

- Absence of mucocytes
- High mitotic rate
- Comprised of ducts and cysts often containing comedo-like necrotic debris sometimes with calcification
- Lumina are lined throughout by atypical cells varying in thickness from one to several layers.
 - In smaller ducts proliferation can fill whole lumen.
 - In larger cysts a variety of architectural patterns can be seen, including Roman bridges, papillary, cribriform.
- Lining cells display variable degrees of nuclear pleomorphism, and central nucleoli may be prominent.
- Cancerization of acini can be identified.
- Strict criteria required for diagnosis including:
 - Absence of local invasion determined by adequate sampling of the whole lesion and presence of an intact myoepithelial layer around all tumor islands ideally confirmed by immunohistochemistry for basal-myoepithelial markers (e.g., CK5/6, CK14, p63, calponin, smooth muscle myosin heavy chain)
- Too few cases to determine with certainty natural history of pure SDCIS but limited cases with adequate follow-up have survived for years following complete excision with no recurrence or progression of disease
- Relationship of SDCIS to low-grade cribriform cystadenocarcinoma (LGCCC) remains unclear:
 - May represent separate entities
 - May represent extreme low-grade end of spectrum of SDCIS
- Rare examples reported in:
 - Setting of carcinoma ex pleomorphic adenoma described with rhabdoid features
 - In association with IgG4-related salivary gland disease
- Histochemistry:
 - Intracytoplasmic diastase-sensitive, PAS-positive material can be seen.
 - Intracytoplasmic mucicarmine staining is usually negative.
 - Intraluminal mucicarminophilic material may be present.
- Immunohistochemistry:
 - Cytokeratins (low and high molecular weight), CK7, EMA, and CEA
 - Androgen receptor (AR):
 - Most cases AR positive
 - Represents characteristic although not pathognomonic finding

- Diffuse GATA-3 (nuclear) staining
- Estrogen and progesterone receptor markers usually negative but 1q or both may be positive in minority of cases
- GCDFFP-15 (BRST-2) may be focally positive.
- *HER-2* (membranous staining) and *EGFR* positive in high proportion of cases
- CK5/6 and p63 focal to absent staining
- S100 protein and markers indicative of myoepithelial differentiation, including calponin, p63, smooth muscle actin, and vimentin are typically negative:
 - Similar to its use in ductal carcinomas of the breast, myoepithelial markers have been used to identify a peripheral non-neoplastic myoepithelial layer that, if identified, may indicate a tumor confined to within a duct (intraductal carcinoma) as opposed to absent staining that may indicate an infiltrative process.
 - However, similar cells can be seen in metastatic foci and reactivity with stromal myofibroblasts may suggest myoepithelial layering and therefore an intraductal process, when in fact the carcinoma is invasive.
- Rare documentation of neuroendocrine differentiation as evidenced by presence of chromogranin and synaptophysin reactivity
- Prostate-specific antigen and prostatic acid phosphatase may be positive.
- High proliferative index ranging from 25% to 80% by Ki-1 (MIB1) staining

NOTE: Molecular classification of SDC similar to breast cancer proposed but clinical relevance remains uncertain; such suggested classification includes (see below):

- Luminal AR-positive SDC
- *HER-2*-positive SDC
- Basal-like SDC
- Electron microscopy:
 - Desmosomes, tight junctions, rough endoplasmic reticulum, mitochondria, basal lamina, and luminal cells with microvilli
- Cytogenetics and molecular genetics:
 - Loss of heterozygosity in chromosome 9p21, 6q, 16q, 17p, 17q regions
 - *ERBB2* (*HER-2*) gene amplification in up to 36% of cases and protein expression from 26% to 100%
 - *EGFR* gene mutation may be present in minority (fewer than 10%) of cases.
 - Frequent *TP53* gene mutation and protein overexpression
 - Deletion of *PTEN* tumor suppressor in majority of cases
 - Apoptosis-related genes *CASP10* and *MMP11* overexpressed

- *CDKN2a/p16* gene inactivation
- *PIK3CA* and *HRAS* mutations recently reported in 33% and 34% of cases analyzed, respectively, and *BRAF* mutation identified in a minority of cases.
- Absence of *MECT1-MAML2* fusion
- Molecular classification of SDC
 - Proposal made to classify SDC into three molecular subtypes analogous to breast cancer
 - Luminal androgen receptor-positive subtype (most common):
 - Androgen receptor positive, *HER-2* negative, CK5/6 negative
 - *HER-2* subtype:
 - *HER-2* immunohistochemical expression 3+, *HER-2/neu* gene amplified
- Basal phenotype (least common):
 - Androgen receptor negative, *HER-2* negative, CK5/6 positive
- Unclassifiable group also identified

Hybrid Tumors

- Hybrid tumors represent the occurrence of a neoplasm composed of two or more histologic distinct types, each of which conforms with an exactly defined tumor category having an identical origin within same topographic area
- Most common tumor types include:
 - Adenoid cystic carcinoma
 - Salivary duct carcinoma
 - Epithelial-myoepithelial carcinoma
- Prognosis predicated on highest histologic grade malignancy (e.g., salivary duct carcinoma)

Differential Diagnosis

- Mucoepidermoid carcinoma, high grade:
 - Consistent CK5/6 and p63 staining that contrasts to SDC showing limited to absent reactivity for these markers
- Adenoid cystic carcinoma
- Acinic cell adenocarcinoma
- Cribriform cystadenocarcinoma (low-grade salivary duct carcinoma); see below
- Oncocytic carcinoma
- Papillary cystadenocarcinoma
- Metastatic mammary carcinoma:
 - Overlapping histologic and immunohistochemical features but rarity of breast cancer metastasizing to salivary glands essentially excludes the diagnosis
- Metastatic prostatic adenocarcinoma:
 - Although SDC may be reactive with prostatic-specific immunomarkers, rarity of prostate cancer metastasizing to salivary glands essentially excludes the diagnosis.

Treatment and Prognosis

- Aggressive management requiring combination complete (radical) surgical extirpation with radical neck dissection and postoperative radiotherapy represent preferred treatment.
- Recurrent disease occurs from approximately one third to two thirds of patients.
- Lymphatic and hematogenous spread occurs:
 - Regional nodal metastases occur in approximately 66% of patients:
 - Nodal metastases may occur at the initial presentation or subsequent
 - Distant metastasis occurs in from 50% to 70% of patients:
 - Most common sites for distant spread include the lungs, bone, and brain.
 - May metastasize to skin
- Mortality rates attributed to this neoplasm are high: from 60% to 80% of patients die from disease within 5 years from the diagnosis.
- Adverse prognostic features include:
 - Tumors greater than 3 cm in diameter
 - Distant metastasis
 - *HER-2* overexpression
 - Micropapillary pattern
 - *CDKN2a/p16* gene inactivation
- Frequent expression of *HER-2*, *EGFR*, and AR in SDC suggest that these receptors can be suitable molecular targets of systemic therapy for patients with SDC:
 - Treatment may include trastuzumab, lapatinib, and bevacizumab individually or in combination.
 - Efficacy of anti-*HER-2* and anti-androgen therapy for receptor-positive SDC yet to be fully proven but preliminarily has shown favorable response

LOW-GRADE INTRADUCTAL CARCINOMA (Figs. 20-113 and 20-114)

Definition: Cystic epithelial salivary gland neoplasm characterized by intraductal epithelial proliferation surrounded by myoepithelial cells composed of histologically low-grade nuclei, absence of infiltrative growth, and overall indolent biologic behavior.

- Likely represents preinvasive phase of an invasive carcinoma (e.g., salivary duct carcinoma, cystadenocarcinoma)
- Strict criteria required for diagnosis, including:
 - Absence of local invasion determined by adequate sampling of the whole lesion and presence of an intact myoepithelial layer around all

Fig. 20-113. Low-grade intraductal carcinoma of the parotid gland.

A, Unencapsulated multicystic proliferation with cribriform growth. **B** and **C**, Cribriform growth composed of cells with apocrine-like features. The cellular proliferation is rather bland composed of relatively uniform-appearing epithelial cells with round nuclei, fine-stippled chromatin and small nucleoli; nuclear pleomorphism is limited and there is no appreciable increase in mitotic activity; necrosis is absent.

tumor islands confirmed by immunohistochemical staining

Synonyms: Low-grade salivary duct carcinoma; low-grade cribriform cystadenocarcinoma (LGCCC); in situ carcinoma

NOTE:

- Classification of this tumor type is controversial and evolving:
 - Initially, considered to represent low-grade variant of salivary duct carcinoma

Clinical

- Rare tumor
- Slightly more common in women than in men; tumor of elderly adults
- Almost exclusively a tumor of parotid gland:

- May exceptionally occur in oral cavity (e.g., palate, tongue)
- Rarely reported as arising within a periparotid lymph node
- Presentation that of slow-growing, asymptomatic mass or swelling

Pathology

Gross

- May show nodular and cystic appearance

Fine-Needle Aspiration Biopsy

- Smears reveal tumor cells arranged in irregular overlapping and show inconspicuous nuclear atypia with variable-sized and irregularly shaped cytoplasmic vacuoles

Fig. 20-114. Low-grade intraductal carcinoma of the oral cavity.

A, Dilated duct with cystic, micropapillary, cribriform, and solid growth. **B**, Cells show moderate nuclear pleomorphism. **C**, Areas showing similar features to atypical ductal hyperplasia of the breast may be identified. **D**, p63 immunoreactivity highlights the myoepithelial cells confirming the proliferation is intraductal.

Histology

- Unencapsulated tumor composed of dominant cyst or multiple variably sized cysts
- Cystic epithelial proliferation shows cribriform and papillary growth patterns with fibrovascular cores:
 - “Roman arches” similar to those seen in relation to mammary lesions
- Cellular proliferation includes:
 - Relatively uniform-appearing epithelial cells with round nuclei, fine stippled chromatin, and small nucleoli
 - Apocrine-appearing cells may represent dominant cell type or may focally be present.
 - Nuclear pleomorphism is limited.
 - No appreciable increase in mitotic activity
 - Comedotype necrosis may or may not be present.
- Myoepithelial cells present and may appear monolayered and attenuated but may not be identifiable by light microscopy requiring immunohistochemical staining for identification (see below).
- In addition to cystic foci, separate ductal epithelial proliferation identified composed of small ducts with cribriform, micropapillary, and solid growth consisting of cells cytologically similar to those seen in cystic foci.
- Transition from low nuclear grade to higher nuclear grade (i.e., intermediate and high grade)
- Invasive carcinoma or micro-invasion reported in up to 23% of cases
- Invasive carcinoma may rarely occur and may be identified in recurrent lesions:
 - Invasion may be in the form of microinvasive carcinoma.
 - Less often, includes presence of solid nests of tumor within adjacent salivary gland parenchyma or connective tissue

- Stromal fibrosis/sclerosis and mixed chronic inflammatory infiltrate may be present, especially in areas of invasive carcinoma.
- Neurotropism and angioinvasion not typically present
- Cells may contain:
 - Apical apocrine-like microvacuoles/globules which are diastase resistant, PAS positive
 - Yellow- to brown-appearing intracytoplasmic pigment resembling lipofuscin
- Immunohistochemistry:
 - Lesional cells:
 - Cytokeratin, EMA, S100 protein positive
 - Calponin, smooth muscle actin, vimentin usually negative
 - Androgen receptor, *HER-2*, and GCDP15 (BRST-2) may be positive
 - Estrogen receptor, progesterone receptor usually negative
 - GATA-3 (nuclear) staining may be focally positive.
 - Low proliferative activity (<5%) seen by Ki-67
 - Myoepithelial cell layer:
 - Reactive for p63, CK14, actins (smooth muscle, muscle specific), calponin

Differential Diagnosis

- Sclerosing polycystic adenosis
- Cystadenoma
- Cystadenocarcinoma
- Acinic cell adenocarcinoma, papillary-cystic variant
- High-grade salivary duct carcinoma in situ

Treatment and Prognosis

- Surgical excision is preferred treatment.
- Excellent prognosis with no reported metastasis or mortality over 2- to 12-year follow up

CYSTADENOCARCINOMA

(Figs. 20-115 through 20-118)

Definition: Malignant epithelial salivary gland tumor characterized by predominant cystic and papillary growth and lacking defining histomorphologic features of another type of salivary gland malignancy.

Synonyms: Papillary cystadenocarcinoma; malignant papillary cystadenoma; low-grade papillary adenocarcinoma of the palate

Clinical

- Rare tumor
- No gender predilection; occurs over a wide age range but the majority of patients are older than the sixth decade of life

Fig. 20-115. Cystadenocarcinoma.

Cystadenocarcinoma of the parotid gland appearing as a predominantly cystic and focally solid lesion.

- Tend to be tumors of major salivary glands, in particular the parotid gland
 - Less often occurs in the sublingual gland and minor salivary glands, including buccal mucosa, palate, lips, floor of mouth, and tongue
- Presentation that of slow-growing, asymptomatic mass or swelling; erosion of bone particularly related to palate tumors may occur:
 - Rarely associated with pain and facial paralysis

Pathology

Gross

- Delineated or partially circumscribed cystic or multicystic mass ranging in size from 0.4 to 6 cm in greatest dimension

Histology

- Circumscribed but unencapsulated cystic or multicystic proliferation separated by fibroconnective tissue or approximating one another
- Cysts haphazardly arranged varying in size and shape
- Lumens may contain mucinous material as well as calcifications; latter may also be present outside the cysts in stroma.

Fig. 20-116. Cystadenocarcinoma, low grade.

A, Cystic and predominantly papillary architecture with fibrovascular cores. **B,** At high magnification the cells are rather uniform with bland-appearing nuclei. The findings could be those of a papillary cystadenoma but invasion was present (not shown), allowing for a diagnosis of a low-grade (papillary) cystadenocarcinoma.

- Small duct-like structures and solid epithelial islands with or without lumens may be identified between cysts:
 - Duct-like structures and solid islands may be infiltrative into non-neoplastic salivary gland parenchyma and/or surrounding fibroconnective tissues.
- Epithelial cell proliferation varies in growth and cell type:
 - Papillary architecture is present in the majority of cases, varying from simple/single papillary projection to multiple papillae and creating a complex papillary to solid appearance that may fill involved lumen.
 - Cribriform growth may be seen especially in cases in which epithelial lining cells become thickened.
 - Cystic epithelial lining cells may form a single layer or multiple layers in thickness.

Fig. 20-117. Cystadenocarcinoma, intermediate grade.

A, Unencapsulated, multicystic and infiltrative parotid gland tumor in which the cysts are haphazardly arranged, vary in size and shape, and show a variable epithelial pattern of growth, including macrocystic, cribriform, and papillary.

B, At high magnification the cells show greater disorganization and nuclear pleomorphism as compared with low-grade neoplasms but not as significant as seen in higher grade neoplasms.

- Most often cell type is small cuboidal, less often larger cuboidal or tall columnar cells
- Other cell type that may be identified include mucous, oncocytic, clear, and epidermoid cells.
- Majority histologically low grade, characterized by:
 - Cytomorphologic uniformity with minimal pleomorphism, although moderate pleomorphism may be present.
 - Prominent nucleoli may be identified.
 - Low to absent mitotic activity
 - Necrosis usually absent
 - Cytomorphologically high-grade nuclear features may be present.
- Histologically higher-grade lesions may occur, including intermediate and high grade:

Fig. 20-118. Cystadenocarcinoma, high grade.

A, Cystic and papillary neoplasm. **B**, Focally intracystic mucinous material may be present. **C**, At high magnification there is marked nuclear pleomorphism and increased mitotic activity.

- Intermediate grade:
 - As compared with low grade, greater degree of nuclear pleomorphism and increased mitotic activity but not reaching levels associated with histologically high-grade neoplasms
- High grade:
 - Marked nuclear pleomorphism, increased mitotic activity, atypical mitoses, and necrosis
- Invasive growth is prerequisite for diagnosis:
 - Invasion may be limited in extent requiring liberal sampling of the resection specimen.
 - Neurotropism may be present in minority of cases (<10%).
- Stromal findings may include:
 - Lymphoplasmacytic cell infiltrate that occasionally may be dense.
 - Ruptured cysts may result in stromal hemorrhage, hemosiderin-laden macrophages, and granulation tissue.
- Histochemistry:
 - Mucin stains are usually negative.

Differential Diagnosis

- Cystadenoma
- Warthin tumor
- Acinic cell adenocarcinoma, papillary-cystic variant
- Mucoepidermoid carcinoma, low grade
- Low-grade intraductal carcinoma
- Salivary duct carcinoma
- Polymorphous low-grade adenocarcinoma

Treatment and Prognosis

- Complete surgical resection is preferred treatment:
 - Parotid gland: superficial parotidectomy with sparing of facial nerve unless involved by tumor
 - Submandibular and sublingual glands: glandectomy
 - Minor salivary glands: wide excision to include tumor-free margins:
 - In presence of osseous invasion that can be seen in palatal lesion, more radical excision is required.
- In absence of clinical evidence of neck disease, neck dissection would not appear to be warranted.
- Recurrence and metastasis (regional and distant) are uncommon, occurring in less than 8% and 10% of patients, respectively.
- To date, no reported tumor-related death

MYOEPITHELIAL CARCINOMA

(Figs. 20-119 through 20-123)

Definition: Malignant salivary gland tumor composed exclusively of cells with myoepithelial differentiation as determined by light microscopic, immunohistochemical,

Fig. 20-119. Myoepithelial carcinoma.

A, Large floor of mouth solid mass with deviation of the tongue. **B**, On imaging the mass is large and infiltrative.

and/or ultrastructural findings, and with invasive growth and metastatic potential:

- Represents malignant counterpart of myoepithelioma.

Synonym: Malignant myoepithelioma

Clinical

- Uncommon tumor
- No gender predilection; tumor of adults with occurrence over wide age range from second to ninth decades of life; mean age at presentation in mid-sixth decade
- Most common site of occurrence is parotid gland
 - Less common sites of occurrence include:
 - Submandibular gland
 - Minor salivary glands:
 - Palate most common
- Presentation usually that of asymptomatic mass or swelling:
 - Duration of symptoms usually from months to years

- Pain, dysphagia, and hoarseness uncommonly may occur.
- Invasion of bone with bone destruction may occur in association palatal tumors.
- May arise:
 - As de novo neoplasm
 - From preexisting pleomorphic adenoma (myoepithelial carcinoma ex pleomorphic adenoma) or myoepithelioma
 - Clinical presentation may be that of a long-standing mass with recent rapid increase in size
 - Alternatively, develops following multiple recurrences
- No known etiologic factors

Pathology

Fine-Needle Aspiration Biopsy

- Aspirates show similar findings to those seen in myoepithelioma (see previous) but with cytologic features indicative of a malignancy, including:
 - Marked nuclear pleomorphism, increased mitotic activity, atypical mitoses, and necrosis

Gross

- Unencapsulated, nodular tumor that on cut section is gray-white and firm, measuring from 2 to approximately 6 cm, although examples can be larger
- Cystic areas and necrosis may be identified.

Histology

- Unencapsulated tumor that may be circumscribed characteristically with nodular or multinodular appearance:
 - Growth patterns include sheets, nests, trabeculae, fascicular, storiform, or cord-like (also referred to as reticular)
- Cellular components similar to those seen in myoepithelial predominant pleomorphic adenomas or in myoepithelioma, including:
 - Spindle-shaped, plasmacytoid (hyaline), epithelioid, and clear cells:
 - Combination of cell types is usually present, although a given tumor may be predominantly or exclusively composed of a single cell type.
 - Epithelioid cell type reported to be most common
- Nuclear pleomorphism varies from case to case and may be mild, moderate, or severe; mitotic activity varies from scarce or few in number to examples with high mitotic rate; necrosis may be present.
- Metaplastic changes, including squamous and sebaceous cells, may be identified.
- Stroma varies from copious amount of mucoid or myxoid-appearing stroma to sparse stromal tissue in markedly cellular tumors:

Fig. 20-120. Myoepithelial carcinoma.

Multiple growth patterns can be seen in myoepithelial carcinomas including (A) large solid nest; (B) fascicular and storiform; (C) trabecular; (D) cordlike/reticular; and (E) microcystic. A variable stroma is present from sparse to fibrous to mucinous appearing.

Fig. 20-121. Myoepithelial carcinoma.

The cell types in myoepithelial carcinoma include (**A** and **B**) spindle-shaped; (**C**) plasmacytoid; (**D**, **E**) epithelioid; and (**F**) clear. The degree of nuclear pleomorphism varies from case to case. In panels **A** and **D** there is limited nuclear pleomorphism, whereas in panels **C** and **E** nuclear pleomorphism is present; note the mitotic figure in panel **E** (arrowhead).

Continued

Fig. 20-121, cont'd

G, Areas of necrosis in a comedotyped pattern may be present.

Fig. 20-122. Myoepithelial carcinoma.

Immunoreactivity in myoepithelial carcinomas includes **(A)** cytokeratin (AE1/AE3); **(B)** p63 (nuclear staining).

- Limited to abundant reduplicated basement membrane-like material appearing as eosinophilic hyaline material may be present.
- Cystic degeneration may be present.
- Although cytomorphologic evidence of malignancy may be readily identified, these findings may not be present and an unequivocal diagnosis is predicated on infiltrative growth, including:
 - Invasion into nonneoplastic salivary gland parenchyma
 - Adjacent fibroconnective tissues
 - Neurotropism
 - Angioinvasion
- By definition, ductal differentiation is not a component except in cases arising in association with a pleomorphic adenoma:
 - Presence of duct differentiation would confer a different designation (e.g., epithelial-myoepithelial carcinoma, others)
 - Presence of duct differentiation in this tumor type is the subject of debate with some authorities allowing for limited ductal differentiation.
- Immunohistochemistry:
 - Pancytokeratin (e.g., AE1/AE3) is consistently reactive.
 - Other cytokeratins including CAM5.2, CK903 (34BE12), CK5/6, CK7, and CK14 are variably expressed.
 - Vimentin positive
 - Immunoreactivity for a marker associated with myoepithelial differentiation should be identified for diagnosis, including:
 - p63, calponin, S100 protein, smooth muscle actin, smooth muscle myosin heavy chain:
 - Smooth muscle actin is seen in spindle-shaped myoepithelial cells but not in plasma-cytoid myoepithelial cells.
 - Desmin and c-kit (CD117) reactivity are uncommonly seen.
 - Myogenin, melanocytic markers negative.
- Electron microscopy:
 - Variable identification of cytoplasmic microfilaments with focal dense bodies, pinocytotic vesicles, desmosomes, basal lamina, and intermediate filaments
- Cytogenetics and molecular genetics:
 - Not known to have *EWSR1* rearrangement(s) with one exception
 - Clear cell variant of myoepithelial carcinoma of major and minor salivary glands (de novo and ex pleomorphic adenoma) shown to harbor *EWSR1* rearrangement:
 - Prognosis of clear cell type of myoepithelial carcinoma with *EWSR1* rearrangement appears to be aggressive with poor clinical outcomes, including:

Fig. 20-123. Myoepithelial carcinoma.

An unequivocal diagnosis of a malignant tumor is predicated on infiltrative growth that may include (A) invasion into parotid gland parenchyma; (B) (left and right) angioinvasion; (C) osseous invasion.

- Increased incidence of nodal metastasis and distant metastasis
- Increased incidence of disease-associated mortality due to disseminated disease

Hybrid Tumors

- Uncommonly may be a tumor type occurring as a hybrid tumor representing occurrence of neoplasm composed of two or more histologic distinct types, each of which conforms with an exactly defined tumor category having an identical origin within same topographic area
- Prognosis predicated on highest histologic grade malignancy (e.g., salivary duct carcinoma)
- High-grade transformation (“dedifferentiation”) of myoepithelial carcinoma
 - Rare examples of transition to histologically higher-grade neoplasm reported
- Secretory myoepithelial carcinoma:
 - Recently described
 - Dual secretory and myoepithelial phenotype

- Mucicarmine-positive vacuolated/signet ring cells embedded in myxoid stroma
- At least focal p63 staining and/or calponin reactivity
- Membranous E-cadherin positive
- FISH negative for ETV6, EWSR1, and ALK1 rearrangements
- Fairly indolent fashion

Differential Diagnosis

- Myoepithelioma:
 - Differentiation may be possible on basis of cytomorphic features in cases of myoepithelial carcinoma with:
 - Marked cellular pleomorphism
 - Increased mitotic activity
 - High proliferation indices (>10%) by Ki67 staining
 - However, as previously noted, in any given example of myoepithelial carcinoma there may not be significant cytomorphic findings to

allow differentiation on such features alone and in such scenarios presence of infiltrative growth differentiates myoepithelial carcinoma from myoepithelioma.

- Epithelial-myoepithelial carcinoma
- Clear cell carcinoma
- Sarcoma (in those cases dominated by a spindle-shaped cellular component):
 - Synovial sarcoma
 - Malignant peripheral nerve sheath tumor
 - Leiomyosarcoma
 - Sclerosing rhabdomyosarcoma:
 - May occur in parotid gland simulating myoepithelial carcinoma
 - Presence of desmin and myogenin and absence of cytokeratin, p63, and S100 protein
- Spindle cell squamous carcinoma (sarcomatoid carcinoma):
 - Cytokeratins and p63 immunoreactivity may be present in spindle cell squamous carcinoma, but typically such tumors lack evidence of other myoepithelial markers, including calponin.
- Metastatic malignant melanoma
- Plasmacytoma
- Soft tissue myoepithelial carcinoma:
 - Primary myoepithelial tumors of soft tissues are uncommon.
 - Classification includes:
 - Benign neoplasm (myoepithelioma) (see under [myoepithelioma](#))
 - Malignant neoplasms (myoepithelial carcinoma)
 - As compared with their salivary gland counterpart:
 - A higher proportion of myoepithelial tumors of soft tissues are malignant.
 - Unlike salivary gland myoepithelial carcinoma, in which a majority arise in association with a pleomorphic adenoma (i.e., myoepithelial carcinoma ex pleomorphic adenoma), this occurrence is rare relative to soft tissue myoepithelial carcinoma, the majority of which occur as a de novo malignancy.
 - Clinical:
 - Sites of involvement:
 - Majority occur in soft tissues outside head and neck most commonly arising in limbs (upper and lower) and girdle with involvement of the subcutis and deep soft tissues
 - Among more common sites of occurrence in head and neck is neck (See Section 4) and craniofacial region
 - Demographics:
 - Occur over a wide age range with many cases affecting pediatric ages but develop in adult populations as well
- Clinical symptoms usually include a mass with or without associated pain.
- Pathology:
 - Most tumors are circumscribed; however, they may have infiltrative margins.
 - Histologically, at low magnification a multinodular or lobular architecture is evident; at periphery of lobules lesion is hypercellular arranged in reticular, trabecular, nests, or solid patterns.
 - Lesional cells may be epithelioid, clear, spindle, or plasmacytoid:
 - Characterized by cytomorphologic heterogeneity; although epithelioid type predominates, majority of cases are composed of more than one myoepithelial cell type
 - Cytologic atypia of at least moderate degree is present, including nuclear enlargement, vesicular to coarse-appearing nuclei, and variably prominent nucleoli.
 - Increased mitotic activity, tumor necrosis, and lymph-vascular invasion may be present.
 - Rare examples with rhabdoid morphology described
 - Stromal component includes myxoid change and/or hyalinization.
 - Cartilaginous differentiation and metaplastic ossification may be present.
 - Immunohistochemical staining:
 - Lesional cells reactive for cytokeratins (AE1/AE3, CAM5.2, PAN-K), EMA, S100 protein, calponin, p63, SMA, MSA, GFAP, CD10, and vimentin
 - CD99 immunoreactivity may be present.
 - Desmin, CD34, and brachyury typically negative
 - Nuclear expression of INI-1 may be lost in a minority of cases; loss of INI1 may be seen in cases with rhabdoid morphology, making distinction from other INI1-negative rhabdoid tumors difficult
 - Well established that myoepithelial carcinomas demonstrate *EWSR1* gene rearrangement, making them genetically distinct from salivary gland counterpart:
 - Identification of *EWSR1-POU5F1* or *EWSR1-PBX1* gene fusion
 - Differential diagnosis rather broad and may include:
 - Extraskelatal myxoid chondrosarcoma, epithelioid malignant peripheral nerve sheath tumor, synovial sarcoma (poorly differentiated), undifferentiated carcinoma, and Ewing sarcoma/PNET

- Treatment and prognosis:
 - Protocols include wide surgical resection for localized tumors and adjuvant radiotherapy with or without nodal dissection.
 - Potential for local recurrence and/or metastases (nodal and viscera).
 - More aggressive behavior occurs in pediatric ages than in adult population, including death from disease.
 - Use of chemotherapy is unproven and appears in limited studies to offer no added benefit.

Treatment and Prognosis

- Complete surgical resection is preferred treatment, which includes:
 - Parotid gland: superficial parotidectomy
 - Submandibular gland: glandectomy
 - Minor salivary glands: wide excision to include tumor-free margins
 - In presence of osseous invasion a more radical excision is required.
- In absence of clinical evidence of neck disease, a neck dissection would not appear to be warranted.
- Radiotherapy used in select situations with mixed outcomes
- Efficacy of chemotherapy not proven
- Behavior of these tumors is variable:
 - Some behave in indolent/low-grade manner.
 - Others behaving more aggressively (intermediate to high grade)
- From 50% to 67% develop recurrent tumor; often multiple recurrences
- Approximately 50% of patients develop metastatic disease:
 - Lung most common site of metastasis
 - Distant metastasis more frequent than regional (nodal) metastasis
- Approximately 30% of patients die of disease.

PRIMARY SQUAMOUS CELL CARCINOMA (SCC)

(Figs. 20-124 and 20-125)

Definition: Malignant epithelial neoplasm of major salivary glands composed of squamous cells characterized by presence of keratinization and/or intercellular bridges:

- Diagnosis predicated on absence of clinical or historical evidence of a squamous cell carcinoma in another (head and neck) site that has metastasized to the salivary gland or invaded directly into the salivary gland from a mucosal or cutaneous primary squamous cell carcinoma
- Diagnosis of primary SCC relative to minor salivary glands not considered appropriate due to the

Fig. 20-124. Parotid squamous cell carcinoma.

Primary squamous cell carcinoma of the parotid presenting as an ulcerated and necrotic, firm mass extending behind the ear, with separate tumor nodules just anterior to the gland, and associated with facial nerve invasion and paralysis. From this appearance and obvious cutaneous involvement, a primary cutaneous carcinoma cannot be ruled out and is clinically the most likely origin rather than originating in the parotid gland. The majority of squamous cell carcinomas of the parotid gland represents secondary involvement from a separate primary cancer rather than being a primary parotid squamous cell carcinoma.

inability to exclude a mucosal squamous cell carcinoma secondarily involving minor salivary glands

Clinical

- Rare tumor
- More common in men than in women; occurs over a wide age range but most frequently identified in the seventh to eighth decades of life; rarely may occur in pediatric ages
- Primarily identified in parotid gland but may also be seen in submandibular gland:
 - In parotid gland nearly all cases identified in superficial lobe
- Most common symptom is mass lesion with or without pain and/or cranial nerve paralysis:
 - Rapid enlargement of the mass may be a presenting complaint.
 - Fixation to adjacent structures and associated ulceration may be present.
 - Duration of symptoms is usually relatively short (within 1 year).
 - Due to high frequency of regional (nodal) metastases at the initial presentation, patients

Fig. 20-125. Parotid squamous cell carcinoma.

A, Although the tumor appears circumscribed and separate from the parotid gland parenchyma (*left*), it was infiltrative with an associated desmoplastic stroma; **B**, trabecular and anastomosing cordlike growth; **C**, keratinizing squamous cell carcinoma histologically similar to squamous carcinomas occurring in more usual sites. Prior to rendering a diagnosis of a primary parotid squamous cell carcinoma, a primary carcinoma of another site (e.g., skin) either with direct invasion of the parotid gland or metastasis to the parotid gland must be excluded.

may also present with cervical lymphadenopathy.

- Cause may be related to prior radiotherapy to head and neck, included for treatment of:
 - Neoplasms
 - Acne
 - Glandular (tonsillar, thyroid, thymic) enlargement
 - Median time frame of 15½ years from radiation exposure to development of carcinoma, with range of 7 to 32 years
 - Not all reported cases of salivary gland squamous cell carcinoma associated with prior radiation exposure

Pathology

Gross

- Unencapsulated, firm to hard, gray to white mass usually measuring more than 3 cm in greatest dimension
- Ulcerated and fixation to adjacent tissues is commonly present.

Histology

- Infiltrating well to moderately differentiated squamous cell carcinoma similar to those occurring in other head and neck sites:
 - Invasive tumor has variable growth patterns including trabecular, nested, or anastomosing cords
 - Intracellular keratin, keratin pearl formation, and intercellular bridges are seen.
 - Presence of keratinization and intercellular bridges confers the designation of squamous rather than epidermoid although these terms have been used interchangeably.
 - Less often, carcinoma is poorly differentiated and/or spindle cell squamous carcinoma but still retains histologic evidence of squamous cell differentiation allowing for classification in this category of tumor rather than another tumor category (e.g., salivary duct carcinoma, undifferentiated carcinoma).
 - Increased mitotic activity and necrosis may be present.
- Invasive tumor includes:
 - Infiltration of adjacent salivary gland parenchyma
 - Invasion into surrounding fibroconnective tissues
 - Neurotropism
 - Angioinvasion
 - Osseous invasion (e.g., mandible, temporomandibular point)
- Tissue invasion often (but not always) produces a desmoplastic response in and around the neoplastic infiltrate.

- A marked chronic inflammatory cell infiltrate occasionally may be associated with the invasive tumor nests.
- Salivary duct changes, including squamous metaplasia and/or dysplasia, may be identified:
 - Transition from normal to dysplastic duct epithelium to squamous cell carcinoma may occasionally (and fortuitously) be identified.
- In patients exposed to radiation, the non-neoplastic salivary gland may show radiation-induced changes, including atrophy and fibrosis.
- May be the malignant component or one of the malignant components of:
 - Carcinoma ex pleomorphic adenoma
 - Malignant transformation of Warthin tumor
- Histochemistry:
 - Special stains for epithelial mucin are negative but should be performed to rule out the presence of high-grade mucoepidermoid carcinoma.
- Immunohistochemistry:
 - Diffuse and strong reactivity for cytokeratins (AE1/AE3, CAM5.2, CK5/6, others) and p63
 - Absence of reactivity for androgen receptor, GATA3, *HER-2*
- Cytogenetics and molecular genetics:
 - No reported *MECT1-MAML2* translocation
- Salivary duct carcinoma:
 - Generally not problematic in differentiating from squamous cell carcinoma but occasional cases may show squamous differentiation or predominance of spindle-shaped cells (i.e., sarcomatoid variant) that in conjunction with high-grade cytomorphology and perhaps absence of ductal differentiation may create problems in differentiating from squamous cell carcinoma:
 - Presence of reactivity for androgen receptor, GATA3 and to a lesser extent *HER-2* should allow for differentiating salivary duct carcinoma or a variant thereof from SCC
- Ductal squamous metaplasia
- Necrotizing sialometaplasia
- Keratocystoma:
 - Histologically characterized by presence of multicystic spaces lined by stratified squamous cells lacking cytomorphologic evidence of malignancy or invasive growth
 - Transformation from parotid ductal epithelium to tumor may be identified.
 - Foreign body giant cell reaction to keratin can be seen.
 - Immunoreactivity for cytokeratin but not for S100 protein or smooth muscle actin; low proliferative rate as determined by Ki-67 (MIB1) staining

Hybrid Tumors

- Uncommonly may be a tumor type occurring as a hybrid tumor, representing occurrence of neoplasm composed of two or more histologic distinct types, each of which conforms with an exactly defined tumor category having an identical origin within same topographic area

Differential Diagnosis

- Nonprimary salivary gland squamous cell carcinoma:
 - More often than not, presence of squamous cell carcinoma in salivary glands represents a nonprimary salivary gland malignancy, either metastatic from a separate primary site or direct invasion from a cutaneous or mucosal-based squamous cell carcinoma
 - Detailed clinical history indicated to determine if the patient has history (current or remote) of a squamous cell carcinoma of another site either within or outside head and neck area
- Mucoepidermoid carcinoma, high grade
- Adenosquamous carcinoma (see Section 5, Larynx, for full description):
 - Represents a mucosal-based carcinoma arising from surface epithelium composed of an admixture of squamous cell carcinoma and adenocarcinoma
 - Rarely if ever develops in major salivary glands
- Treatment and Prognosis
 - Complete surgical excision (e.g., parotidectomy, submandibular glandectomy) is preferred treatment:
 - Direct involvement of facial nerve is not uncommon, often necessitating facial nerve resection.
 - Neck dissection:
 - Owing to high rate of nodal metastases routine neck dissection advocated
 - High rate of microscopic nodal metastases in patients with no palpable cervical lymphadenopathy (clinical N0 neck)
 - Adjunctive radiotherapy may be beneficial in controlling local disease and/or may improve survival.
 - Treatment failure as manifested by local recurrence and/or metastatic disease common
 - Survival rates include:
 - 5-year of 24%
 - 10-year of 18%
 - 15-year of 17%
 - 20-year of 17%
 - Adverse prognostic findings include:
 - Presence of ulceration or fixation
 - Older-aged patients (greater than 60 years)
 - Larger tumors (T3 or greater)
 - Higher-stage tumor

- Most patients with salivary gland squamous cell carcinoma present with higher clinical stage tumors
- Facial paralysis
- Deep tissue fixation
- Prognosis does not correlate to the histology.

LYMPHOEPITHELIAL-LIKE CARCINOMA (LEC)

(Figs. 20-126 and 20-127)

Definition: Undifferentiated carcinoma with associated prominent non-neoplastic lymphoplasmacytic cell infiltrate:

- Histologic features similar to nasopharyngeal carcinoma, nonkeratinizing undifferentiated type

Synonyms: Undifferentiated carcinoma; lymphoepithelioma-like carcinoma; lymphoepithelial-like carcinoma; undifferentiated carcinoma with lymphoid stroma; malignant lymphoepithelial lesion; carcinoma ex lymphoepithelial lesion

Clinical

- Rare salivary gland tumor
- Unique ethnic and demographic features:
 - Predilection for Arctic region natives (Eskimos/Inuits from Alaska, Canada, Greenland), South-eastern Chinese and Japanese
 - Highest incidence worldwide of salivary gland lymphoepithelial carcinoma is in Eskimo/Inuit population
 - Familial predisposition reported:
 - Inherited trichoepitheliomas also reported in this setting, suggesting hereditary predisposition
 - In Eskimos/Inuits:
 - More common in women
 - Predilects to the parotid gland
 - More aggressive clinical course presents with higher clinical stage disease.
- In general, occurs over a wide age range with most patients in the fifth decade of life
- Most common site of occurrence is in the parotid gland (80%) followed by the submandibular gland with rare occurrence in minor salivary glands throughout the upper aerodigestive tract.
- Presentation is usually that of a mass swelling with or without associated pain and/or facial nerve paralysis:
 - Fixation to skin and/or underlying structures seen in advanced tumors
 - High frequency (10% to 40%) of concurrent cervical lymphadenopathy
- Most develop de novo but may arise in association with lymphoepithelial sialadenitis (LESA):

- Possibility that presence of LESA represent reactive process and not precursor lesion
- No known association with other autoimmune disorders (e.g., Sjögren disease)
- Etiology:
 - Linked to Epstein-Barr virus:
 - Near 100% association in patients from endemic areas
 - In non-endemic areas EBV is usually absent, but may rarely be identified
 - Presence of EBV in clonal episomal form suggests role in tumor development
 - Elevated serologic titers of anti-EBV viral capsid antigen IgA, anti-EBV nuclear antigen IgG seen in the majority of patients from endemic regions.

Pathology

Gross

- Circumscribed but unencapsulated, lobulated, firm, tan-white mass measuring from 1 to 10 cm in greatest dimension

Fine-Needle Aspiration Biopsy

- Carcinoma cells variably seen in smears in cohesive aggregates or individual cells and include medium to large size cells with large vesicular-appearing nuclei, one or more prominent nucleoli, high nuclear-to-cytoplasmic ratio
- Associated mature lymphocytes and plasma cells are typically numerous.

Histology

- Infiltrative tumor characterized by presence of lobules, sheets, nests, islands, trabeculae, or cords of neoplastic cells separated by or overrun by lymphoid stroma
- Neoplastic cells are polygonal to spindle-shaped with large round to oval, basophilic to vesicular-appearing nuclei, one or more prominent nucleoli, and abundant amphophilic to lightly eosinophilic cytoplasm
- Cells have indistinct cell borders and syncytial growth is usually evident.
- Moderate to marked nuclear pleomorphism present
- Increased mitotic activity and necrosis seen
- Squamous differentiation may be present.
- Prominent basaloid morphology may be seen (basaloid LEC):
 - Identified in Inuit population
 - Associated with EBV
- A dense non-neoplastic lymphoplasmacytic cell infiltrate with or without germinal centers is present:
 - Identified between and around tumor nests or may overrun and obscure presence of epithelial component

Fig. 20-126. Lymphoepithelial-like carcinoma of the parotid gland.

A and **B**, Infiltrative but circumscribed cellular proliferation separated from the adjacent parotid gland parenchyma (left) that includes clusters of lighter staining neoplastic foci in a background of dense lymphocytic cell infiltrate including germinal centers. Note the absence of an associated desmoplastic reaction to the infiltrative neoplasm. **C**, Cohesive cluster of neoplastic cells characterized by cells with enlarged vesicular nuclei, prominent eosinophilic nucleoli, and indistinct borders creating a syncytial growth. These histologic features are similar to nasopharyngeal carcinoma, nonkeratinizing undifferentiated type. The lesional cells are (**D**) cytokeratin positive; (**E**) p63 positive (nuclear staining); and (**F**) positive by in situ hybridization for Epstein-Barr encoded RNA (EBER).

Fig. 20-127. Lymphoepithelial-like carcinoma of the parotid gland.

Variant histologic features may include (A) fascicular growth with spindle-shaped neoplastic cells that were cytokeratin and p63 reactive (not shown) and also (B) EBER positive; (C) basaloid cell features that were cytokeratin and p63 reactive (not shown); and also (D) EBER positive.

- Abundant histiocytes may be seen creating a “starry sky” appearance
- Noncaseating granulomatous inflammation may be identified.
- An amyloid stroma may also be present.
- Invasion is present, including into non-neoplastic salivary gland parenchyma, surrounding connective tissues, neurotropism, and angioinvasion.
- Immunohistochemistry:
 - Epithelial cells:
 - Cytokeratins and EMA positive
 - p63 positive but variable reactivity may be present from case to case and even within the same case
 - c-kit (CD117) reactivity may be present
 - p16 negative
 - Lymphoid cells:
 - Reactive for B-cell (CD20) and T-cell (CD3) markers
- Epstein-Barr virus:
 - In-situ hybridization for Epstein-Barr encoded RNA (EBER) consistently positive in cases from endemic regions
 - Usually negative but can occasionally be positive in cases from nonendemic regions
- Electron microscopy:
 - Epidermoid cell features, including desmosomes, tonofilaments, and cytoplasmic microfilaments

Differential Diagnosis

- Metastatic EBV-associated carcinoma
 - Overlapping histologic, immunohistochemical, and molecular features
 - Differentiation predicated on detailed clinical evaluation to exclude primary nasopharyngeal or less commonly oropharyngeal carcinoma
- Metastatic HPV-associated oropharyngeal carcinoma:

- Presence of p16 and/or identification of high-risk HPV by molecular testing (PCR, ISH) and absence of EBV would allow for differentiation.
- Malignant lymphoma
- Lymphoepithelial sialadenitis
- Malignant melanoma
- Nonsebaceous lymphadenoma

Treatment and Prognosis

- Combined (multimodality) therapy, including surgical resection, neck dissection, and radiation therapy preferred treatment:
 - Up to 40% of patients may present with regional lymph node metastasis.
- Local recurrence and distant metastasis may occur.
- 5-year survival rate reported to be 75% to 86%
- Prognosis linked to clinical stage

NEUROENDOCRINE CARCINOMAS

- Represent group of malignant neoplasms with epithelial and neuroendocrine differentiation
- Classification includes:
 - Typical carcinoid (well-differentiated neuroendocrine carcinoma)
 - Atypical carcinoid (moderately differentiated neuroendocrine carcinoma)
 - Small cell neuroendocrine carcinoma (poorly differentiated neuroendocrine carcinoma)
 - Large cell neuroendocrine carcinoma (poorly differentiated neuroendocrine carcinoma)
- Rare tumor type in salivary glands:
 - In salivary glands, primarily involve parotid and much less often submandibular gland
 - Most common type is small cell neuroendocrine carcinoma.
 - Rarely, atypical carcinoid and large cell neuroendocrine carcinoma may arise in salivary glands

Small Cell Undifferentiated (Neuroendocrine) Carcinoma (Figs. 20-128 and 20-129)

Definition: Malignant salivary gland tumor composed of undifferentiated small cells showing epithelial and neuroendocrine differentiation:

- Histologically similar to pulmonary counterpart
- May in fact be better considered as neuroendocrine carcinoma, Merkel cell type (see below)

Synonyms: Small cell carcinoma; extrapulmonary oat cell carcinoma; neuroendocrine carcinoma; poorly differentiated neuroendocrine carcinoma

Clinical

- Rare primary salivary gland tumor
- Slightly more common in men than women; occur over a wide age range but most common in the fifth to seventh decades of life
- Most common site of occurrence is the parotid gland (80% of cases); less common sites include the submandibular gland, sublingual gland, and minor salivary glands:
 - Minor salivary gland involvement includes intra-oral sites, as well as throughout the upper aerodigestive tract.
- Presentation usually that of rapidly enlarging and painless mass
 - Facial nerve paralysis commonly present (60%)
 - Duration of symptoms is typically short, occurring over several months
 - Cervical lymphadenopathy fairly common finding at presentation
- Neuroendocrine cells originating from the neural crest migrate to a variety of sites including to salivary glands (major and minor salivary glands):
 - Neuroendocrine cells identified in intercalated ducts and seromucous acini
- Rarely, patients present or have an associated paraneoplastic syndrome.

Pathology

Gross

- Poorly circumscribed, multilobulated, firm, gray-white mass; infiltration into adjacent structures may be evident.
- Hemorrhage and necrosis may be identified.

Histology

- Infiltrative tumor growing in diffuse sheets, cord, trabeculae, ribbons, or irregular nests:
 - Associated fibrous and/or fibrovascular stroma with or without hyalinization may be present.
- Histologically may be classified into:
 - Pulmonary subtype:
 - Absence of CK20 reactivity
 - Merkel cell subtype:
 - Presence of CK20 reactivity
 - May or may not show expression of Merkel cell polyoma virus (MCPyV)

Pulmonary Subtype

- Infiltrative neoplasm with diffuse, cord-like, trabecular growth and variable fibrovascular stroma
- Lesional cells are rather uniform composed of round to oval nuclei with dispersed (stippled) appearing nuclear chromatin, inconspicuous to small nucleoli, minimal cytoplasm, and indistinct cell borders:

Fig. 20-128. Small cell (neuroendocrine) carcinoma, pulmonary type, of the parotid gland.

A, Hypercellular tumor (*left*) infiltrative in the parotid gland (*right*). **B**, Growth patterns include diffuse or sheet-like and trabecular. **C**, Confluent focus of necrosis. **D**, Small cells with hyperchromatic nuclei, dispersed (stippled) appearing nuclear chromatin, inconspicuous nucleoli, minimal cytoplasm, and indistinct cell borders; nuclear molding, mitotic figures and individual cell necrosis are present. Lesional cells are immunoreactive for **(E)** cytokeratin (CAM5.2) with dot-like paranuclear staining and **(F)** synaptophysin. Staining for CK20 was negative (not shown).

Fig. 20-129. Small cell (neuroendocrine) carcinoma, Merkel cell type, of the parotid gland.

A, Intraparotid infiltrative neoplasm appearing as cohesive clusters and trabeculae; an associated inflammatory cell infiltrate is present. **B**, Lesional cells are uniform, composed of round to oval nuclei with pale or washed out chromatin. The lesional cells are immunoreactive for **(C)** CK20 with a paranuclear dot-like staining pattern; **(D)** synaptophysin and **(E)** Merkel cell polyoma virus (nuclear staining). In addition to CK20, other cytokeratins including AE1/AE3 and CAM5.2 were positive with paranuclear dot-like staining pattern (not shown).

- Cell are approximately two times larger than mature lymphocytes, but occasionally larger tumor cells may be present.
- Fusiform to polygonal shaped cells may occasionally be present.
- Crush artifact resulting in nuclear clumping and diffusion of chromatin material may be identified
- Nuclear molding and peripheral nuclear palisading may be present.
- Tumor necrosis readily apparent either as confluent foci of necrosis or individual cell necrosis
- A high mitotic rate, including atypical mitoses, is present.
- Neural-type rosettes including pseudorosettes (Homer Wright-type) or true rosettes (Flexner-Wintersteiner-type) may be identified.
- Immunohistochemistry:
 - Cytokeratins positive, including pancytokeratin (AE1/AE3), CAM 5.2:
 - Typically shows a punctate or globular paranuclear pattern of staining
 - EMA positive
 - p63 may be positive and if present tends to be focal or scattered positive cells
 - CK7 and CK20 negative
 - Neuroendocrine marker(s) positive, including at least one of the following:
 - Synaptophysin, chromogranin, CD56
 - Neuron-specific enolase positive
 - S100 protein is usually negative.
 - No immunoreactivity for Merkel cell polyoma virus (MCPyV), thyroid transcription factor 1 (TTF-1), melanocytic cell markers (HMB45, melan A, tyrosinase, MITF1), hematolymphoid markers (leukocyte common antigen), myogenic markers (desmin, actins, myogenin, myoglobin), or vimentin
- Electron microscopy:
 - Membrane-bound neurosecretory granules
 - Sparse cytoplasmic organelles; well to poorly formed desmosomes

Merkel Cell Type

- Sheet-like growth
- Lesional cells rather uniform composed of round to oval nuclei with pale or washed out chromatin described as “blown up balloons”:
 - Minimal nuclear molding
- Immunohistochemistry:
 - Similar to pulmonary subtype except for the presence of CK20 reactivity
 - Merkel cell polyoma virus (MCPyV):
 - Discrepant findings in the literature with some reports documenting presence of MCPyV while other reports document absence of MCPyV

- Rarely, foci of ductal differentiation and squamous differentiation may be seen:
 - Tumors with ductal differentiation have been termed ductal-type of small cell carcinoma.
- Small cell carcinoma may rarely be the malignant component in carcinoma ex pleomorphic adenoma.

Hybrid Tumors

- Uncommonly may be a tumor type occurring as a hybrid tumor, representing occurrence of neoplasm composed of two or more histologic distinct types, each of which conforms with an exactly defined tumor category having an identical origin within same topographic area

Other Histologic Types of Salivary Gland Neuroendocrine Carcinomas

- In addition to small cell neuroendocrine carcinoma, other types of salivary gland neuroendocrine carcinomas are rare but may include:
 - Typical carcinoid (well-differentiated neuroendocrine carcinoma):
 - Extraordinarily rare parotid tumor with scattered reports that appear to indicate parotid involvement occurred secondary to a primary carcinoid of a separate site
 - Atypical carcinoid (moderately differentiated neuroendocrine carcinoma):
 - Invasive malignant neoplasm characterized by trabecular, solid, and focally organoid growth patterns
 - Lesional cells characterized by round to oval nuclei with dispersed (“salt and pepper” or neuroendocrine type) chromatin and granular eosinophilic-appearing cytoplasm
 - Mild to moderate nuclear pleomorphism
 - Increased mitotic activity
 - Necrosis (individual cell and confluent “comedotype”)
 - Neural-type rosettes may be identified.
 - Infiltrative growth may include invasion of salivary gland parenchyma, perineural invasion, lymph-vascular invasion
 - Immunohistochemical staining:
 - Lesional cells reactive for:
 - Cytokeratins (AE1/AE3, CAM5.2) with punctate paranuclear staining,
 - Neuroendocrine markers including chromogranin, synaptophysin, CD56
 - p63 may be positive.
 - Negative for CK20, melanocytic cell markers, S100 protein, CD45, calcitonin, TTF1, and MCPyV
 - Large cell neuroendocrine carcinoma:
 - Requisite pathologic criteria include all four of the following:

- Tumor cells with moderate to abundant cytoplasm
- Features of neuroendocrine differentiation (organoid nesting, trabecular growth, rosettes, and peripheral palisading)
- Mitotic activity > 10/10 hpf (2 mm²)
- Confirmation of neuroendocrine differentiation using immunohistochemical staining for chromogranin-A, synaptophysin, neuron-specific enolase, and/or neural cell adhesion molecule (CD56)
- Other typical but not requisite findings include:
 - Nuclei with prominent nucleoli
 - Cellular pleomorphism
 - Large areas of necrosis

Differential Diagnosis

- Metastatic small cell (neuroendocrine) carcinoma of lung (or other) origin
- Metastatic Merkel cell carcinoma
- Adenoid cystic carcinoma, solid variant:
 - Cribriform growth and rather diffuse reactivity for p63, calponin, and absence of neuroendocrine markers assist in diagnosis.
- Malignant lymphoma
- Malignant melanoma
- Rhabdomyosarcoma

Treatment and Prognosis

- Combined multimodality therapy, including surgical resection, regional lymph node dissection, and adjunctive radiotherapy, represents preferred treatment.
- Local recurrence and metastasis occur in approximately 50% of patients:
 - Hematogenous spread is more common than lymphatic spread.
 - Distant metastatic sites include liver and brain.
- Chemotherapy has been used with questionable efficacy in patients with recurrence and distant metastases.
- Survival rates include:
 - 2-year of 70%
 - 5-year of 46%
- Adverse prognostic findings include:
 - Tumor size:
 - Tumors greater than 4 cm more apt to demonstrate neurotropism, invasion of surrounding soft tissues, and increased incidence of local failure.
- Better prognosis associated with:
 - Merkel cell subtype
 - Smaller tumor size (<4 cm)

LARGE CELL UNDIFFERENTIATED CARCINOMA (Fig. 20-130)

Definition: High-grade malignant epithelial salivary gland tumor lacking evidence of glandular, squamous or neuroendocrine differentiation and an inability to classify in another (more specific) salivary gland carcinoma.

Clinical

- Extraordinarily rare salivary gland tumor type
- No gender predilection; tumor of adults with patients usually in seventh to eighth decades
- No ethnic or racial predilection or association with EBV (unlike lymphoepithelial carcinoma)
- Majority of parotid gland origin:
 - Submandibular gland, lacrimal gland, and minor salivary glands may rarely be primary sites of occurrence
- Presentation usually that of rapidly enlarging mass often with associated facial nerve paralysis and cervical lymphadenopathy; fixation to adjacent tissues is commonly present.

Pathology

Fine-Needle Aspiration Biopsy

- Isolated and loosely cohesive large cells with abundant cytoplasm, and variably pleomorphic nuclei with prominent nucleoli
- Multinucleated tumor giant cells and macrophage polykaryons may be present.
- No evidence of squamous, myoepithelial, or widespread mucinous differentiation
- Focal rare mucin production may be identified on special stains.

Gross

- Poorly circumscribed, obviously invasive, firm, solid, gray-white mass measuring from 2 to 10 cm in greatest dimension
- Hemorrhage and necrosis are often identified.

Histology

- Widely invasive tumor composed of sheets, nests, and trabeculae lacking evidence of specific cellular differentiation and separate by a fibrous stroma.
- Lesional cells:
 - Large usually measuring greater than three times the size of cells in small cell neuroendocrine carcinoma
 - Usually polygonal with enlarged round to oval, vesicular nuclei, one or more prominent nucleoli, abundant amphophilic to eosinophilic cytoplasm and rather distinct cell borders

Fig. 20-130. Large cell undifferentiated carcinoma of the parotid gland.

A, Intraparotid infiltrative neoplasm appearing as a nodular focus with diffuse growth; **(B)** diffuse (sheet-like) growth; **(C)** at high magnification the lesional cells are characterized by markedly enlarged and pleomorphic round to oval nuclei with vesicular nuclear chromatin, prominent eosinophilic nucleoli, and indistinct eosinophilic cytoplasm. Increased mitotic activity is present. There is an absence of any type of cellular differentiation (e.g., squamous, glandular, other). The lesional cells were only reactive for several different cytokeratins including **(D)** OSCAR.

- Alternative cytoplasmic findings include vacuolated to partially clear appearance.
- Nuclear pleomorphism commonly seen but occasional cases may display nuclear uniformity
- Increased mitotic activity including atypical mitoses and tumor necrosis commonly identified
- Multinucleated (osteoclast-like) giant cell may be identified.
- Invasion readily apparent including into non-neoplastic salivary gland parenchyma, surrounding connective tissues, perineural invasion, and lymphovascular invasion.
- Desmoplastic stroma that may include benign lymphoplasmacytic cell infiltrate but does not approach the density and/or extent seen in lymphoepithelial carcinoma.
- May represent the dedifferentiated cellular component of a number of differentiated salivary gland tumors (e.g., acinic cell adenocarcinoma, others) and may be the malignant component or one of the malignant components seen in carcinoma ex pleomorphic adenoma.
- Histochemistry:
 - Stains for epithelial mucin are negative.
 - Intracytoplasmic glycogen (diastase-sensitive, PAS-positive) may be present.
- Immunohistochemistry:
 - Cytokeratins positive (pancytokeratin, others)
 - CK20 negative
 - Should be negative for neuroendocrine markers:
 - Presence of neuroendocrine markers may result in classification large cell type of

neuroendocrine carcinoma if requisite histologic features are present (see above)

- Melanocytic, hemolymphoid and mesenchymal markers negative
- EBV negative (by immunohistochemistry and/or in situ hybridization)
- p16 negative
- Cytogenetics and molecular genetics:
 - TP53 mutations
 - Loss of heterozygosity at chromosome 17p

Differential Diagnosis

- Squamous cell carcinoma, poorly differentiated
- Adenocarcinoma, NOS, poorly differentiated
- Mucoepidermoid carcinoma, high grade
- Cystadenocarcinoma, poorly differentiated
- Large cell neuroendocrine carcinoma
- Malignant lymphoma
- Malignant melanoma
- Sarcomas
- Metastatic carcinoma to salivary glands from separate primary carcinoma

Treatment and Prognosis

- Radical surgical extirpation with postoperative radiotherapy represents preferred treatment.
- Chemotherapy has been used in treatment with varying success.
- Aggressively behaving tumor with high rate recurrence and metastases (regional and distant).
- Prognosis is poor:
 - 36% 2-year survival
- Factors adversely affecting prognosis include:
 - Large tumor size (4 cm or greater)
 - Age >50 years
- Metastatic disease

ONCOCYTIC CARCINOMA

(Fig. 20-131)

Definition: Malignant salivary gland epithelial tumor predominantly or exclusively composed of oncocytic cells with cytomorphologic features of malignancy (adenocarcinomatous features) and invasive growth but lacking findings that might allow classification into another tumor type.

Synonyms: Malignant oncocytoma; oncocytic adenocarcinoma; malignant oxyphilic adenoma

Clinical

- Exceedingly rare tumor type
- More common in men than in women; most frequently occurs in the fifth through eighth decades of life

- Occur predominantly but not exclusively in the parotid gland (80%)
 - Other sites of occurrence may include:
 - Submandibular gland and much less often in association with minor salivary glands
- Presents as mass or swelling with or without associated pain and/or facial nerve paralysis
 - Cervical lymphadenopathy at presentation is fairly common.
- May arise as a de novo neoplasm or in association with a long-standing benign oncocytoma
 - Cases occurring in association with oncocytoma may present with rapid enlargement of a preexisting mass lesion.
 - Rarely occur following radiation treatment

Pathology

Fine-Needle Aspiration Biopsy

- Aspirates show similar findings to those seen in oncocytoma (see [Oncocytoma](#)).
- Cytologic features indicative of a malignancy, including marked nuclear pleomorphism, increased mitotic activity with atypical mitoses, and necrosis may not be present.

Gross

- Unencapsulated single or multinodular, firm mass lesion with tan-gray appearance; foci of necrosis may be present.

Histology

- Partially encapsulated or unencapsulated lesion showing varied growth patterns, including sheets and nests of neoplastic cells infiltrating surrounding tissues with loss of normal lobular architecture
- Lesional cells characterized by:
 - Presence of large, round to oval cells with abundant granular eosinophilic cytoplasm due to the absolute increase in the number of cytoplasmic mitochondria
 - Nuclei tend to be enlarged, centrally located, round to oval, with vesicular chromatin and often with prominent nucleoli.
 - Ductal differentiation may be present.
 - Oncocytic cells may form pseudoluminal spaces.
- Nuclear pleomorphism varies from case to case and even within the same case:
 - Any given tumor may demonstrate foci with absent nuclear pleomorphism adjacent to or admixed with cells showing moderate to marked nuclear pleomorphism.
 - These features raise possible occurrence of an oncocytic carcinoma arising in association with oncocytoma.

Fig. 20-131. Oncocytic carcinoma of the parotid gland.

A, The tumor is unencapsulated and infiltrative into parotid parenchyma, appearing as multiple discrete nodules. A variety of growth patterns can be seen, including **(B)** trabecular, cord-like, and solid; **(C)** complex back-to-back glandular-appearing (pseudoluminal) spaces and cysts. **D** and **E,** The lesional cells are characterized by the presence of cells with prominent granular eosinophilic-appearing cytoplasm but vary in their degree of pleomorphism from case to case and even within a given case including **(D)** limited nuclear pleomorphism and **(E)** moderate to marked nuclear pleomorphism. Irrespective of the presence or absence of nuclear pleomorphism these are malignant neoplasms that may include **(F)** perineural invasion and/or

**Fig. 20-131, cont'd****(G)** nodal metastasis.

- Increased mitotic activity, including atypical mitoses and necrosis (coagulative type), may be present.
- Invasion is present and includes:
 - Infiltration of non-neoplastic salivary gland parenchyma
 - Surrounding connective tissues
 - Neurotropism and/or lymph-vascular invasion
- Histochemistry:
 - Stains for mitochondria including Novelli and phosphotungstic acid hematoxylin (PTAH) show purplish and blue cytoplasmic granules, respectively.
 - Stains for epithelial mucin are negative.
- Immunohistochemistry:
 - Cytokeratin positive, including pancytokeratin (AE1/AE3), CK7, CK8, and CK19
 - CEA and EMA positive
 - S100 protein, p63, calponin, smooth muscle actin negative
 - Antimitochondrial antibodies, used infrequently, may be of assistance in the diagnosis.
 - Increased proliferative activity as determined by Ki-67 (MIB1) staining may be present.
- Electron microscopy:
 - Numerous mitochondria that vary in size and shape
 - Desmosomes, nearly continuous basal lamina and lumina with microvilli, are present.

Differential Diagnosis

- Oncocytoma:
 - Generally devoid of nuclear pleomorphism, increased mitotic activity, and coagulative necrosis
 - Necrosis and/or infarction may be present, especially following traumatic events such as

fine-needle aspiration biopsy, and such findings should not be construed as evidence of malignancy.

- Rare examples of (encapsulated) oncocytoma with metastatic tumor reported (so-called metastasizing oncocytoma):
 - Primary tumor showed minimal cytologic atypia.
 - Nodal metastasis at presentation
 - Distant metastases months after diagnosis
 - Patient died 18 months after diagnosis.
- Oncocytosis
- Salivary gland tumors with oncocytic cells as either an admixed cellular component or the predominant component, including:
 - Mucoepidermoid carcinoma
 - Acinic cell adenocarcinoma
- Salivary duct carcinoma
- Metastatic carcinoma with oncocytic features, including origin from the kidney, pancreas

Treatment and Prognosis

- Treatment is complete surgical excision that often necessitates total parotidectomy; nodal dissection is advocated given the increased incidence of regional (nodal) metastasis.
- Efficacy of radiotherapy in treatment of these tumors has not been definitively proven.
- Behavior is that of a high-grade malignancy:
 - Tendency to recur (56%)
 - Tendency to metastasis (80%), including regional lymph nodes and distant metastases
 - Distant metastases occur to lungs, kidney, mediastinum, liver, bone, and thyroid gland.
 - Distant metastasis is associated with poor prognosis, resulting in tumor-related death within 4 years.

MALIGNANT SEBACEOUS TUMORS

Sebaceous Carcinoma

(Figs. 20-132 and 20-133)

Definition: Malignant epithelial salivary gland neoplasm with infiltrative growth composed of islands and sheets of atypical cells, including sebaceous cells of varying maturity.

Synonym: Sebaceous adenocarcinoma

NOTE: Cells with sebaceous differentiation may be seen in other salivary gland neoplasms including (but not limited to) pleomorphic adenoma, oncocytomas, Warthin tumors, basal cell adenoma, mucoepidermoid carcinoma, acinic cell adenocarcinoma, adenoid cystic carcinoma.

Fig. 20-132. Parotid gland sebaceous carcinoma.

Sebaceous carcinoma of the parotid gland appearing as a circumscribed, tan-white to yellowish mass.

Clinical

- Rare neoplasm
- No gender predilection; bimodal age distribution with peak incidences in third decade and seventh and eighth decades
- Majority occur in parotid gland:
 - Rare cases identified in oral cavity, vallecula, submandibular gland, sublingual gland, and epiglottis.
- Most common symptom is that of a slow-growing mass or swelling with or without associated pain and/or facial nerve paralysis:
 - Cutaneous fixation may be present.

Pathology

Gross

- Circumscribed or partially encapsulated, yellow to tan-white mass measuring from 0.6 to 8.5 cm in diameter with pushing or infiltrative margins

Histology

- Encapsulation may be present but these lesions demonstrate at least focally infiltrative margins:
 - Infiltration includes into surrounding fibroconnective tissue and/or salivary gland parenchyma
- Growth patterns include solid, sheet-like, irregular islands or nested:
 - Coalescence into large solid sheets may occur.
 - Numerous and occasionally cystic well-formed ductal structures seen:
 - Cells lining ducts are cuboidal to low columnar with abundant eosinophilic cytoplasm
- Neoplastic cells are mostly characterized by squamous or basaloid cell types both outnumbering sebaceous cells:

- Variable degree of sebaceous differentiation:
 - In some cases very few easily overlooked, appearing in small clusters of individual cells
 - In some cases large islands of sebaceous cells are seen in association with squamous and basaloid cells
 - Sebaceous cells are large with hyperchromatic nuclei and abundant clear to eosinophilic cytoplasm.
- Squamous and basaloid cells show cytologic atypia, including:
 - Enlarged, moderate to marked pleomorphic and hyperchromatic nuclei
 - Increased mitotic activity including atypical forms and necrosis may be present.
- Invasive growth including:
 - Perineural invasion (20%)
 - Angioinvasion is uncommon.
- Oncocytes, mucocytes, and foreign body giant cells may rarely be identified.
- Histochemistry
- Immunohistochemistry
 - Sebaceous cells:
 - EMA positive

Differential Diagnosis

- Sebaceous adenoma
- Metastatic sebaceous carcinoma from orbital or cutaneous sites

Treatment and Prognosis

- Surgical excision (subtotal or total parotidectomy) is preferred treatment.
- Adjunctive radiotherapy and chemotherapy have been used, but of questionable efficacy in controlling disease
- Appear to behave as low-grade to intermediate-grade neoplasms:
 - Local recurrence may occur.
 - Metastatic disease (regional lymph node or to distant sites) may develop late in the disease course.
 - 5-year survival rates are reported to be approximately 62%.
 - Appears to be a more aggressive neoplasm than its counterpart in orbit

Sebaceous Lymphadenocarcinoma

Definition: Malignant counterpart of sebaceous lymphadenoma from which it arises.

Clinical

- Rare tumor with only five reported cases in world literature to date

Fig. 20-133. Salivary gland sebaceous carcinoma.

Sebaceous carcinoma of the parotid gland. **A**, At the extreme left is parotid parenchyma from which the tumor originates and invades as solid cellular nodules with sheet-like growth into skeletal muscle. **B** through **D**, Cytologic features include a predominant basaloid cell proliferation with admixed larger sebaceous cells with abundant clear to eosinophilic-appearing cytoplasm. **E**, Lesional cells are EMA positive.

- More common in men than woman; majority were in seventh decade of life with one in sixth decade and one in fourth decade
- All of parotid origin except one purported to arise in periparotid lymph node
- Most common presentation was that of a painless mass or swelling; one had associated pain on palpation
 - Duration of symptoms includes 1 month, 2.5 years, 3 years, 10 years, and 20 years.

Pathology

Gross

- Partially encapsulated, yellow-tan-appearing lesion

Histology

- Histologic features are those of sebaceous lymphadenoma characterized by presence of sebaceous cell nests admixed with salivary ducts in a lymphoid background (with or without germinal centers) sharply demarcated from foci of carcinoma characterized by marked nuclear pleomorphism, increased mitotic activity, atypical mitoses and invasive growth including into adjacent parotid parenchyma and perineural invasion:
 - Carcinoma may include malignant sebaceous cells with ductal differentiation, poorly differentiated carcinoma, adenoid cystic carcinoma, undifferentiated carcinoma, and epithelial-myoepithelial carcinoma
 - Carcinomatous foci tend to lack lymphoid cell stroma.
- A foreign body giant reaction may be seen.
- Immunohistochemistry:
 - Variably staining in carcinomatous component, including:
 - For EMA, cytokeratins
 - Increased proliferation rate by Ki67 staining
 - p53 overexpression may be present.

Differential Diagnosis

- Sebaceous lymphadenoma

Treatment and Prognosis

- Surgical resection is preferred treatment.
- Postoperative radiotherapy may be beneficial.
- Given the rarity of this tumor with limited available follow-up information prognosis remains uncertain; of the reported cases with ample follow-up:
 - Three are alive and free of disease at 2, 6, and 14 years, respectively.
 - One patient died of unrelated causes.
 - One patient had pulmonary metastasis.

MUCINOUS ADENOCARCINOMA (Fig. 20-134)

Definition: Salivary gland epithelial malignancy characterized by presence of extracellular mucinous pools or lakes containing neoplastic epithelial cells.

Synonym: Signet ring adenocarcinoma

Clinical

- Rare salivary gland tumor
- Slightly more common in men than in women; occurs over a wide age range but most patients are in seventh decade of life or older:
 - Reported in patient in second decade of life
- Occur in minor salivary glands and major salivary glands:
 - In minor salivary glands, most common in oral cavity, particularly palate:
 - Other intraoral sites include buccal mucosa, lip, and tongue
 - Among major glands submandibular gland appears to be most commonly involved.
 - Presentation includes slow-growing, painless mass or swelling; occasionally may be associated with pain
 - Mucosal-based lesions may have associated ulceration.

Pathology

Fine-Needle Aspiration Biopsy

- Aspirates may include monomorphic, moderately atypical cells, single and clustered, associated with abundant mucoid material and focal necrosis.
- Tumor cells have eccentric nuclei, prominent nucleoli, and occasional cytoplasmic vacuolization.
- Binucleated and multinucleated tumor cells may be present.

Gross

- Tend to be soft in consistency due to prominent mucinous content with a glistening to gelatinous appearance; tumors range in size from 2.5 to 7 cm in greatest dimension.

Histology

- Characterized by presence of cystic cavities containing extracellular mucinous pools within which are epithelial cells appearing in clusters, nests, cords, or individual cells:
 - Epithelial cells appear to float in mucinous material.
 - Cavities separated by fibroconnective tissue
- Lesional (epithelial) cells:
 - Show varying architectural patterns, including branching cords, papillae, cribriform, solid

Fig. 20-134. Mucinous adenocarcinoma of the parotid gland.

A and B, This was an intraparotid neoplasm characterized by glands “floating” in mucous pools. **C,** Extracellular and intracytoplasmic mucin positive material is present.

clusters and lumens, or incomplete duct-like structures

- Are cuboidal to polygonal to columnar with hyperchromatic nuclei and abundant eosinophilic to clear to vacuolated-appearing cytoplasm:
 - Nuclear pleomorphism ranges from mild to moderate
 - Mitotic activity tends to be few to scarce.
- Histochemistry:
 - Extracellular mucinous material:
 - Mucicarmine positive
 - Diastase resistant, PAS positive
 - Intracytoplasmic mucin and diastase-resistant, PAS-positive material may be identified.
- Immunohistochemistry:
 - Cytokeratins including AE1/AE3, CK7, CK8, CK18, and CK19 positive
 - No immunoreactivity for CK20, CDX2, villin
 - Absence of myoepithelial, acinar, and neuroendocrine cell markers
 - Estrogen receptor and progesterone receptor negative

Differential Diagnosis

- Mucoepidermoid carcinoma
- Salivary duct carcinoma, mucin-rich variant:
 - De novo or arising in association with pleomorphic adenoma (i.e., mucin-rich salivary duct carcinoma ex pleomorphic adenoma)
- Colonic (or intestinal)-type adenocarcinoma of oral minor salivary glands:
 - Rare tumor reported to occur at base of tongue or anterior tongue occurring in absence of primary colonic adenocarcinoma:
 - To date, only four reported cases in the literature
 - One patient with 10-month history of occupational exposure to sawdust while working in hardware store prior to development of base of tongue tumor
 - Histologically similar to sinonasal intestinal-type adenocarcinoma (see Section 1, Sinonasal Tract) including presence of submucosal-based infiltrative neoplasm composed of admixture of well- to moderately differentiated colonic-type adenocarcinoma characterized by tubular/glandular structures with an associated mucinous component
 - Immunohistochemical staining includes:
 - Cytokeratins including AE1/AE3, CAM5.2, CK7
 - CK20, CDX-2 (nuclear staining), and villin positive
 - CEA, EMA positive
 - Nuclear staining for hMLH1, hMSH2, hMSH6, and hPMS-2 mismatch repair proteins reported

- No *KRAS* mutations of codons 12, 13, and 61 by DNA sequencing
- Metastases to cervical lymph nodes (unilateral or bilateral)
- Histogenesis uncertain but possibilities include:
 - Origin from transformed minor salivary duct epithelium at this location
 - Development from heterotopic gastrointestinal tissue
- Tendency to metastasize to regional cervical lymph nodes (unilateral or bilateral)
- One patient with long-term follow-up remained disease free for 14 months before developing multiple bilateral pulmonary metastatic disease and died from his disease 5 years after diagnosis.
- Cystadenocarcinoma, mucinous
- Cutaneous mucinous (eccrine) carcinoma
- Metastatic mucinous (colloid) carcinoma, including gastrointestinal, pancreatic, breast, sinonasal origin

Treatment and Prognosis

- Surgical resection is preferred treatment.
- Local recurrence in approximately 33%
- Aggressive tumors:
 - Most present with advanced clinical stage disease
 - Cervical node metastasis in 63%
 - Distant metastases in 29%
 - Death from disease in 47%

SIALOBLASTOMA (Fig. 20-135)

Definition: Rare congenital/perinatal low-grade malignant salivary gland tumor composed of basaloid cells and occasional ductal structures recapitulating primitive salivary gland anlage with unpredictable biologic behavior.

Synonyms: Embryoma; congenital basal cell adenoma; congenital carcinoma; low-grade basaloid adenocarcinoma; hybrid basal cell adenoma-adenoid cystic carcinoma

Clinical

- Very rare salivary gland tumor that to date number less than 50 cases reported in the world literature
- More common in males than in females; majority occurs in newborns or shortly after birth; less often, can occur in children over 2 years of age:
 - Rare purported cases reported in adults (see below under Differential Diagnosis with [adenoid cystic carcinoma](#))
- Essentially limited to parotid gland and submandibular gland:
 - Parotid gland >> submandibular gland
 - One case of eyelid in infant presumptively arising from lacrimal gland (palpebral lobe) reported

- One case reported in anterior cheek of infant presumptively arising in ectopic salivary gland tissue
- Presenting symptom(s) usually that of asymptomatic parotid or submandibular gland mass:
 - May include rapid growth
 - Rarely, may be associated with facial paralysis
 - May be fixed either to underlying structures or to skin with or without ulceration
- Radiology:
 - MRI may show a large facial mass, which is mostly hypointense to the brain and isointense with muscle on T1-weighted images, and mildly hyperintense on T2-weighted images and high-intermediate signal intensity similar to that of fat on T2-weighted images
 - Foci of hemorrhage and necrosis may be present.
 - Invasion into adjacent structures such as the maxilla and adjacent muscles may be present.
- Elevated levels of alpha-fetoprotein may be present.
- Association with hepatoblastoma and congenital nevi reported

Pathology

Fine-Needle Aspiration Biopsy

- Cytologic features include presence of variably arranged, tight, solid clusters of atypical-appearing, basaloid-like cells in a background of dispersed epithelial and myoepithelial cells.
- Clusters contain an admixture of benign ductal cells and dense, metachromatic, magenta hyaline globular material with smooth, rounded outlines.
- Cytologic findings show complete concordance with the histology of sialoblastoma.

Gross

- Circumscribed to partially encapsulated, nodular or lobulated, solid lesion with a tan-gray to yellow appearance, usually firm, measuring from 1.5 to 15 cm.
- Hemorrhage and necrosis may be present.

Histology

- May vary from being well circumscribed/semienapsulated and noninfiltrative to infiltrative, which may include:
 - Infiltration into adjacent structures such as salivary gland parenchyma
 - Facial nerve invasion
- Cellular neoplasm composed of a combination of solid islands of basaloid cells as well as ductal structures, which recapitulate appearance of the developing fetal salivary gland.
 - Hypercellular islands separated by fibrous or fibromyxomatous stroma

Fig. 20-135. Sialoblastoma.

A, Intraparotid infiltrative tumor characterized by lobular and nodular growth separated by varying degrees of fibroconnective tissue. **B** and **C**, The combination of solid islands of basaloid cells with admixed ductal structures recapitulate the appearance of the developing fetal salivary gland and is characteristic for sialoblastoma. **D**, At higher magnification the basaloid cells are primitive appearing with large round to ovoid vesicular to hyperchromatic nuclei; the ductal component includes small ducts with identifiable lumina lined by cuboidal to low columnar-appearing cells with eosinophilic cytoplasm; intraluminal secretory material is present.

- Islands may be tightly packed (i.e., solid growth) with little intervening (fibrovascular) stroma or may be loosely arranged with abundant intervening stroma.
- Basaloid cells:
 - Primitive-appearing with large round to ovoid vesicular nuclei, ample eosinophilic cytoplasm, one or more nucleoli, and indistinct cell borders
 - Vague peripheral nuclear palisading may be seen.
- Ductal component:
 - Small ducts have distinct lumina.
 - Lined by cuboidal to low columnar cells with eosinophilic cytoplasm can be present
 - Ductal lumina may contain basophilic secretory material.
- Favorable and unfavorable histologic patterns identified, including:
 - Favorable:
 - Semiencapsulation with cytologically bland basaloid tumor cells showing mild nuclear pleomorphism, identifiable mitoses but absent atypical mitoses, absent necrosis, and presence of intervening stroma:
 - Unfavorable:
 - Presence of anaplastic tumor cells, increased mitotic activity including atypical mitoses, necrosis, minimal stroma, and presence of broad pushing infiltrative periphery
- Cribriform growth similar in pattern to that seen in adenoid cystic carcinoma may be present.

- Other cell types that may occasionally be present include sebaceous, squamous, and acinar cells; calcification may also be seen.
- Malignant spindle cell (sarcomatoid) component rarely identified:
 - Spindle cells cytokeratin and S100 protein positive
 - Considered sarcomatoid transformation of basaloid (myoepithelial) cell component
- Immunohistochemistry:
 - Basaloid cells:
 - Diffuse reactivity for CK903 (34BE12); variable to absent expression of other keratins and EMA
 - Diffuse p63 reactivity
 - Positive staining often focal for S100 protein, calponin, smooth muscle actin
 - GFAP negative
 - Alpha-fetoprotein expression may be present (reported in cases with unfavorable histology)
 - Ductal cells:
 - Reactivity for cytokeratins including diffuse or focal luminal staining for pancytokeratin, CAM5.2, CK5/6, CK7, and CK903 (34BE12), as well as EMA
 - Focal S100 protein may be present.
 - Negative for CK20, p63, smooth muscle actin, calponin, and GFAP
- Proliferative indices may vary from low levels (<5% cases with favorable histology) to markedly increased levels (50% to >90% with unfavorable histology)
- p53 (nuclear) staining may be focal or diffuse in both cellular components
- Electron microscopy:
 - Cell junctions present between ductal and surrounding tumor cells
 - Basaloid cells have well-developed endoplasmic reticulum, free ribosomes, and surrounding basal lamina
 - Intracytoplasmic thin filaments and subplasmalemmal densities can be seen in peripheral cells:
 - Based on presence of actin immunoreactivity and intracytoplasmic thin filaments, cells surrounding ductal cells are believed to be of myoepithelial origin.

Differential Diagnosis

- Basal cell adenoma:
 - Basal cell adenomas in contrast to sialoblastoma occur in adults (rare prior to age 20) and are noninvasive and composed of less primitive cells, greater peripheral nuclear palisading, less cytomorphologic atypia, and less mitotic activity.
- Basal cell adenocarcinoma
- Adenoid cystic carcinoma:
 - Diagnosis of adenoid cystic carcinoma rare in neonates and infants:
 - Tumor with hallmark features of sialoblastoma but with cribriform growth in neonates or infants should be diagnosed as sialoblastoma.
 - Sialoblastoma in adults rarely if ever occurs, and in adults any degree of cribriform growth would result in classification of a tumor with features of sialoblastoma as an adenoid cystic carcinoma; however:
 - Three adult tumors with primitive histopathologic findings characteristic for sialoblastoma including cribriform growth reported:
 - Included 46-year-old female, 55-year-old male, and 83-year-old male
 - Two cases of palate and one of parotid
 - Differences in clinical behavior in these cases from adenoid cystic carcinoma cited as evidence to support diagnosis as sialoblastoma rather than adenoid cystic carcinoma including prolonged disease-free interval over long-term follow-up
 - Nevertheless, if confronted with such a lesion in adults, diagnosis of sialoblastoma in lieu of adenoid cystic carcinoma cannot be rendered with complete confidence, and treatment should follow that for adenoid cystic carcinoma.

Treatment and Prognosis

- Surgical resection with negative resection margins is preferred treatment:
 - In majority of cases results in cure
- Local recurrence reported in approximately 25% of patients:
 - Occur from months to a few years after resection
 - Local recurrences have been associated with increased nuclear pleomorphism, increased mitotic activity, necrosis, and increased proliferation indices.
- Regional nodal metastasis infrequently occurs.
- Chemotherapy (vincristine, actinomycin D, and cyclophosphamide) considered effective adjuvant or neoadjuvant treatment option for unresectable, recurrent or metastatic tumor
- Biologic behavior (presence or absence of recurrence and/or metastatic disease) may correlate to:
 - Histologic features:
 - Tumors with unfavorable histology (see above) associated with more aggressive biologic behavior
 - Proliferation indices and p53:
 - Increase proliferation rate and diffuse p53 staining associated with more aggressive biologic behavior

Fig. 20-136. Parotid malignant lymphoma.

MALT lymphoma of the parotid gland diffusely involving the gland with nodular and tan (fish-flesh) appearance.

NONEPITHELIAL MALIGNANT SALIVARY GLAND TUMORS

Primary Malignant Lymphoma (PML) of Salivary Glands

(Figs. 20-136 through 20-141)

Definition: Malignant neoplastic proliferation of lymphoid cells arising in salivary glands with involvement of glandular epithelium.

- Diagnosis predicated on absence of malignant lymphoma (ML) of noncontiguous site
- If ML of noncontiguous site identified by clinical staging and bulk of tumor is not in the salivary gland, then the salivary gland involvement is considered secondary.
- Complicating issue is presence of intraparotid lymph nodes, which may give rise to ML and therefore are nodal based.
- The distinction between a nodal-based ML secondarily involving parotid glandular epithelium from an ML originating in the parotid gland with secondary nodal involvement cannot always be determined.
- Most ML of salivary glands are non-Hodgkin lymphomas (NHL).
- Salivary gland NHL may develop essentially in two settings:
 - In setting of immune sialadenitis (Sjögren syndrome) with lymphoepithelial sialadenitis (LESA ML):
 - Most often extranodal marginal zone B-cell lymphoma (EMZBCL), which is a low-grade B-cell lymphoma arising in mucosal-associated lymphoid tissue (MALT) referred to as

Fig. 20-137. Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue type.

A and B, Lymphomatous cells coalesce around and infiltrate into the characteristic lymphoepithelial lesions. **C,** At higher magnification the neoplastic (monocytoid B) cells are monomorphic with abundant, pale to clear cytoplasm and uniform-appearing nuclei.

Fig. 20-138. MALT lymphoma.

Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue type. Immunohistochemical staining includes (A) *left panel*, leukocyte common antigen in the lymphomatous cells but not epithelial cells; *right panel*, cytokeratin reactivity in the lymphoepithelial lesions but not lymphomatous cells. B, Lesional cells are CD20 reactive (*left panel*) but nonreactive for CD3 (*right panel*); scattered CD3 positive T-cells are present.

extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)

- As a *de novo* process unrelated to other diseases such as lymphoepithelial sialadenitis (non-LESA ML)
- Most often a diffuse large B-cell lymphoma (DLBCL)
- Rare salivary gland tumor:
 - Represents less than 5% (range 2.4% to 4.5%) of all primary extranodal NHL and approximately 2% of all salivary gland tumors:
 - Extranodal lymphoma includes those patients with stage IE or IIE disease.
 - Lymphomas of extranodal sites in patients with stage IIIIE and IV disease are considered to represent disseminated (systemic) disease rather than primary extranodal lymphoma.

Fig. 20-139. Diffuse large B-cell lymphoma of the parotid gland.

The gland is replaced by a homogeneous tan ("fish-flesh")-appearing proliferation.

- Excluded from category of primary extranodal lymphoma is relapse of nodal-based lymphoma in an extranodal site.
- Given the above, prior to rendering a diagnosis of a primary extranodal lymphoma, detailed clinical staging evaluation is indicated.
- In addition to immune sialadenitis (Sjögren syndrome) ML salivary glands are also closely linked to patients with hepatitis C virus (HCV) infection, suggesting a possible role in the pathogenesis of these lymphomas.
- Risk of developing a ML in patients with immune sialadenitis is markedly increased:
 - Risk of developing salivary gland NHL 44 times greater than control groups
 - Slightly less than 10% of patients with immune sialadenitis develop ML of extranodal sites including:
 - Salivary glands, lacrimal gland, lungs
 - Many of these patients develop benign atypical lymphoproliferative disorders.

MALT Lymphoma

Clinical

- Most common salivary gland lymphoma type
- Decided female predilection; occurs with wide age distribution but, in general, tends to occur in elderly people with mean age in mid-seventh decade of life:
 - 5% or less of patients with salivary gland NHL are younger than fifth decade of life.
 - Rarely, salivary gland NHL may occur in pediatric ages.

Fig. 20-140. Diffuse large B-cell lymphoma of the parotid gland.

A, Diffuse cellular proliferation effacing the parotid parenchyma with infiltration into the adjacent parotid parenchyma (*lower right of center*). **B**, Diffuse dyscohesive cellular proliferation composed of large cells with pleomorphic, vesicular nuclei, and eosinophilic nucleoli.

- Most often occurs in parotid gland, including approximately 75% of all cases
 - Less often, submandibular gland involvement occurs (from 17% to 20% of cases).
- Usual presentation includes slow growing salivary gland mass:
 - Cervical lymphadenopathy may be present at presentation in approximately 30% of patients.
- Presentation may also include ocular, oral, and extraglandular signs, including keratoconjunctivitis sicca and xerostomia:
 - Approximately one third have bilateral enlargement of affected salivary glands.
 - Salivary gland enlargement may be episodic or chronic.
 - Early diagnosis of MALT lymphomas in patients with immune sialadenitis (Sjögren

Fig. 20-141. Diffuse large B-cell lymphoma of the parotid gland.

Immunohistochemical staining shows the neoplastic cells to be *left panel*, CD45 (leukocyte common antigen) positive and *right panel* CD20 positive. The neoplastic cells were nonreactive for cytokeratins and T-cell markers (not shown).

syndrome) but without signs of pre-existing lymphoma may be possible by labial salivary gland biopsies as a routine part of screening for Sjögren syndrome

- In approximately 25% serum monoclonal component (IgG or IgM) may be identified.
- Occurs in association with immune sialadenitis (Sjögren syndrome):
 - Less often may occur with other associated diseases, including:
 - Rheumatoid arthritis, systemic lupus erythematosus, hypothyroiditis
 - In addition to immune sialadenitis also closely linked to patients with hepatitis C virus (HCV) infection, suggesting a possible role in the pathogenesis of these lymphomas:
 - HCV characterized by sialotropism and ability to replicate in salivary glands as well as by lymphotropism
 - Patients with HVC but without Sjögren syndrome not known to have increased risk of lymphoma in salivary glands
 - Overall importance of HCV in pathogenesis of ML arising in Sjögren syndrome remains uncertain
- Risk of developing an ML in patients with immune sialadenitis markedly increased:
 - Risk of developing salivary gland NHL 44 times greater than control groups
 - Slightly less than 10% of patients with immune sialadenitis develop ML of extranodal sites including:
 - Salivary glands, lacrimal gland, lungs

- Many of these patients develop benign atypical lymphoproliferative disorders.
- *Chlamydomydia psittaci* (Cp) implicated in ocular adnexa MALT lymphoma:
 - Cp infection identified in small percentage of patients with Sjögren syndrome developing lymphoma, suggesting its possible role in development of salivary gland lymphoma in patients with Sjögren syndrome

Pathology

- Characteristics include:
 - Occurs in setting of LESA with residual histologic evidence of LESA, including lymphoepithelial lesions
 - Nodular or diffuse (confluent) cellular infiltrate with partial or total effacement of normal lobular architecture:
 - Separate tumor foci may be seen.
 - Presence of “halo” formation surrounding lymphoepithelial lesions distorting or effacing salivary gland parenchyma:
 - Monocytoid and centrocyte-like cells coalesce and surround lymphoepithelial lesions
 - Represents early change
 - May link several or multiple lymphoepithelial lesions
 - Normal lobular architecture altered with replacement of acini and ducts and invasion of the neoplastic cells into surrounding structures
 - Heterogeneous B-cell infiltrate present including:
 - Sheets of lymphoid cells, monomorphic, medium-sized cells with abundant, pale cytoplasm and bland, uniform nuclei, and distinct cell membranes
 - Atypical small lymphocytes
 - Centrocyte-like (cleaved) cells
 - Monocytoid B-cells
 - Immunoblasts
 - Lymphoplasmacytic cells
 - Plasma cells:
 - May be numerous
 - May show intranuclear inclusions (Dutcher bodies) or intracytoplasmic PAS-positive immunoglobulin crystals can be seen.
 - Reactive germinal centers
 - Clusters of epithelioid histiocytes may be present around lymphoepithelial lesions.
 - Ductal dilatation creating a cystic or multicystic appearance not infrequently seen:
 - Presence of cysts vary in size from small to greater than 0.5 cm.
 - Amyloid deposition rarely may be present.
 - Transformation to higher grade lymphoma, usually DLBCL, may occur.
- Immunophenotype (recapitulates that of marginal zone cells)
 - Express CD20, CD79a, CD21, and CD35
 - CD5, CD23, CD10, and cyclin D1 negative
 - Aberrant coexpression of CD43 may be present in approximately 50% of cases:
 - Indicative of neoplastic phenotype
 - Immunoglobulin light chain restriction:
 - Typically IgM; less often IgA or IgG; IgD negative
 - Expressed by lymphocytes and monocytoid B cells, and usually plasma cells
 - Bcl-2 positive (but absent in reactive germinal center cells)
 - Nonreactive for T-cell markers
 - Cytokeratin immunoreactivity limited to lymphoepithelial lesions:
 - May be of assistance in cases where lymphoepithelial lesions are overrun and obscured by lymphoid cells.
- Cytogenetic and molecular genetics:
 - Of chromosomal translocations strongly associated with marginal zone lymphoma, only t(14;18) involving *IgH* and *MALT1* fusion present in proportion of cases ranging from 0 to 18%
 - Other translocations strongly associated with marginal zone lymphoma not seen in salivary gland include:
 - t(11;18) involving *AP1* and *MALT1*; translocation most frequently present in gastric (and lung) MALT lymphoma
 - t(1;14) involving *BCL10* and *IGH*
 - t(3;14) involving *FOXP1* and *IGH*
 - Clonality by itself is insufficient to diagnose lymphoma in setting of LESA as monoclonality in LESA does not necessarily predict clinical or morphologic evidence of lymphoma
 - Nonlymphomatous monoclonal lesions might be considered borderline lesions.
 - Chromosomal abnormalities, including trisomies 3 and 18

Differential Diagnosis

- Lymphoepithelial sialadenitis (LESA):
 - Absence of “halo” formation formed by coalescence of monocytoid and centrocyte-like cells around lymphoepithelial islands, retention of normal salivary gland lobular architecture, absence of increased plasma cells with or without Dutcher bodies assists in differentiating LESA from MALT lymphoma
- Chronic sialadenitis
- HIV-associated salivary gland disease

- Mantle cell lymphoma:
 - Less heterogeneous population of atypical lymphoid cells as compared with EMZBCL
 - CD5, CD43, and cyclin D1 immunoreactivity contrast immunoreactivity of EMZBCL
- Other low-grade lymphomas:
 - Follicular lymphoma:
 - May present diagnostic difficulties with MALT lymphoma when there is follicular colonization
 - CD10, bcl-6, and bcl-2 immunoreactivity contrasts with immunoreactivity of MALT lymphoma
 - In presence of follicular colonization marginal zone neoplastic cells are bcl-2 negative.
- Most often occurs in parotid gland (approximately 75% of all cases)
 - Less often, submandibular gland involvement occurs (from 17% to 20% of cases).
- Majority arise de novo:
 - Some patients may have history of Sjögren syndrome.
 - Rare patients have history of Sjögren syndrome and hepatitis C (HCV) infection.
- Patients present with painless swelling of affected gland(s).
 - Mass is nontender, firm, and often fixed to adjacent tissues.
 - Pain and tenderness uncommonly occur.
- Increased incidence in patients with immunodeficient conditions:
 - Epstein-Barr virus identified in some of these lymphomas

Treatment and Prognosis

- Local therapy including surgery or radiotherapy
- Survival rates include:
 - 5-year survival of 85% to 90%
 - 15-year relative survival was 78.4%
- Relatively indolent behavior usually remains localized:
 - Majority are Ann Arbor stage IE or IIE disease:
 - 54% IE
 - 19% IIE
 - 10% IIIE/IV
 - Relapses not uncommon and may involve:
 - Primary site lymph nodes, especially cervical neck, and extranodal sites
 - Relapses can be treated successfully.
 - Dissemination is slow to occur and may involve cervical lymph nodes and other mucosal sites.
 - Excellent prognosis for low-grade lymphoma with localized disease (IE)
 - Prognosis for nodal involvement (IIE) is similar to that of primary low-grade nodal-based NHL.
- MALT lymphomas may transform to DLBCL:
 - Occurs in approximately 12% of cases
 - Tumors tend to follow a more aggressive course, including death, but may have a more favorable prognosis than comparable nodal disease.

Diffuse Large B-Cell Lymphoma (DLBCL)

Clinical

- Represents approximately 10% of salivary gland PML
- Slight female predilection; wide age distribution but, in general, tendency to occur in elderly people with mean age in mid-seventh decade of life

Pathology

Gross

- Circumscribed to ill-defined and infiltrative lesion
- Cut surface appears tan-white to yellow-tan with a homogeneous (“fish-flesh”) appearance and firm consistency.

Histology

- Characterized by:
 - Diffuse replacement of salivary gland tissue with effacement of the normal lobular architecture:
 - Lymphoma cells infiltrate and replace acini and ducts.
 - Infiltration into adjacent connective tissue structures seen that may include perineural invasion
 - Extraglandular spread into surrounding periglandular soft tissues occurs.
 - Neoplastic cells are large with round to oval enlarged nuclei, vesicular chromatin, and prominent eosinophilic nucleoli.
 - Lymphoepithelial islands (LEIs) not seen
 - Immunophenotype:
 - Express CD45 and various pan-B markers including CD20, CD79a, PAX5
 - CD20 lost in 60% of recurrent tumors treated with rituximab
 - Monotypic surface or cytoplasmic immunoglobulin frequently seen (IgM > IgG > IgA)
 - Melanoma-associated antigen (MIM1) expression (nuclear staining)
 - BCL6 expression in approximately 60%
 - CD10 expression in 20% to 40%
 - CD5 expression in approximately 10%
 - CD30 expression in approximately 10%

- BCL6 expression in approximately 50%
- Ki67 index >20% (mean 55%)
- May be p63 positive
- Cytogenetic and molecular genetics:
 - Clonal rearranged immunoglobulin heavy- and light-chain genes
 - Rearranged germline T-cell receptor (TCR) genes
- Small number of cases of DLBCL have a component of marginal zone lymphoma
 - Likely represent transformation of MALT lymphoma to DLBCL
 - Associated with more aggressive behavior

Differential Diagnosis

- Lymphoepithelial sialadenitis (LESA)
- IgG-related sialadenitis
- Sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease)
- Carcinoma (undifferentiated, others):
 - Immunoreactivity for epithelial markers (cytokeratins, others) and absence of immunoreactivity for hematolymphoid markers allow for differentiation.

Treatment and Prognosis

- Treatment and prognosis similar to histologically identical lymphomas of lymph nodes:
 - Treatment may include combination of surgical resection, radiotherapy, and chemotherapy.
- Most patients have localized disease.

Other Types of Salivary Gland Non-Hodgkin Lymphomas

- Other types of NHLs may involve salivary glands, including:
 - Follicular lymphoma:
 - In different studies varies from second most common (to MALT lymphoma) or third most common (to MALT lymphoma and DLBCL) type of salivary gland lymphoma
 - Mantle cell lymphoma, anaplastic large cell lymphoma, extranodal NK/T cell lymphoma of nasal type, and peripheral T-cell lymphoma

Hodgkin Lymphomas of Salivary Glands

- Primary involvement of salivary glands by Hodgkin lymphoma is rare.
- Classical and nodular lymphocyte predominant type
- Majority occurs in parotid gland and likely represents secondary spread from nodal-based disease.

SARCOMAS OF SALIVARY GLANDS

Clinical

- Sarcomas of salivary glands are extremely uncommon, accounting for less than 2% of all malignant salivary gland tumors and approximately 0.5% of all salivary gland tumors.
- This category excludes carcinosarcoma (previously discussed under Malignant Mixed Tumors).
- Sarcomas of salivary glands tend to occur in older-aged patients.
- Most sarcomas involve the parotid gland.
- Presentation includes mass or swelling with or without pain and/or facial nerve paralysis; a rapidly enlarging mass occurs in a minority of patients.
- Virtually all sarcoma types have been reported to occur in salivary glands; more common types include:
 - Malignant peripheral nerve sheath tumor
 - Fibrosarcoma
 - Undifferentiated pleomorphic sarcoma
 - Rhabdomyosarcoma
 - Angiosarcoma
 - Synovial sarcoma
 - Leiomyosarcoma
 - Kaposi sarcoma:
 - Often occurs in HIV-positive patients
 - Develop in the parotid gland or intra- or periparotid lymph nodes
 - Liposarcoma
 - Alveolar soft part sarcoma
 - Others:
 - Recently rare case of adamantinoma-like Ewing sarcoma reported as primary parotid neoplasm:
 - *EWSR1* and *FLI1* fluorescence in situ hybridization confirmed presence of translocation supporting diagnosis
 - *EWSR1* identified in salivary gland hyalinizing clear cell carcinoma
- Prior to diagnosis of a primary sarcoma of salivary glands, clinical evaluation indicated to:
 - Exclude a history of a histologically similar sarcoma of a separate and/or adjacent (e.g, soft tissues of neck) primary site
 - Exclude metastasis to involved salivary gland from a separate primary site or direct invasion into the salivary gland from an adjacent primary site
 - Confirm origin from within the involved salivary gland
- Diagnosis and differential diagnosis based on light microscopic features often requiring adjunct studies, including histochemistry, immunohistochemistry,

electron microscopy, cytogenetics to confirm the diagnosis

- Depending on tumor type the differential diagnosis may include (but is not limited to) carcinomas (especially in those sarcomas with epithelioid features) and malignant melanoma.
- Treatment usually requires complete surgical resection combined with radiation and chemotherapy.
- Because sarcomas are more likely to spread hematogenously rather than via lymphatic channels, unless there is clinical evidence of neck disease, cervical (nodal) neck dissection would not appear to be warranted.
- Prognosis is dependent on a variety of factors including:
 - Stage of disease
 - Tumor size
 - Sarcoma type
 - Histologic grade
- Recurrence occurs from 40% to 64% of patients:
 - Most recurrences occur within 1 year following treatment.
- Distant metastases occur in 40% to 64% of patients.
- Tumor-related death ranges from 36% to 64%.
- Overall 5-year and 10-year survival rates of 42% and 20%, respectively

SECONDARY TUMORS

Definition: Salivary gland involvement by malignant tumor originating from separate primary site that has spread to involved salivary gland by direct invasion from an adjacent site or via hematogenous or lymphatic spread from a distant site.

Clinical

- Metastatic disease to salivary glands uncommon, representing approximately 5% of all malignant salivary gland tumors.
- Much more common in men than in women; peak incidence is in the seventh to eighth decades of life although may occur in any age group including the

very young (infants and children) and the very old (tenth decade and older).

- Majority of cases involve parotid gland, and to a lesser extent submandibular gland:
 - Metastases may occur to intraparotid lymph nodes and secondarily involve parotid parenchyma.
- Relative to parotid gland, the majority (80%) of secondary tumors originate from head and neck neoplasms.
- Relative to the submandibular gland, the majority (85%) of secondary tumors originate from distant sites.
- Most common secondary tumors involving salivary glands are cutaneous squamous cell carcinoma and malignant melanoma.
- For primary tumors that originate from distant (non-head and neck) sites, most common tumor types metastasizing to salivary glands are of lung (especially small cell neuroendocrine carcinoma), kidney, and breast origin:
 - In contrast to renal clear cell carcinoma, clear cell carcinomas of salivary glands are:
 - Nonreactive for renal cell carcinoma antibody, CD10, PAX2, PAX8, CAIX
 - Demonstrate presence of *EWSR1* translocation.
 - In rare examples of simultaneously occurring salivary duct carcinoma and primary mammary duct carcinoma differentiation can be problematic given overlapping histologic features and immunohistochemical staining:
 - Differentiation possible if primary breast cancer is histologically low grade as salivary duct carcinomas are histologically high grade

Intraoperative Consultation in Salivary Glands and Biopsy

Diagnosis of Salivary Gland Neoplasms

INTRAOPERATIVE CONSULTATION IN SALIVARY GLANDS

General Considerations

(Figs. 21-1 through 21-12)

- Intraoperative consultation (i.e., frozen section) in salivary gland pathology presents unique diagnostic challenges.
- Majority of salivary gland neoplasms (approximately 80%) originate in parotid and submandibular glands:
 - Approximately 20% to 25% of neoplasms occurring in major salivary glands are malignant.
 - In parotid gland, most neoplasms arise in superficial lobe
- Majority of minor salivary gland neoplasms originate in the oral cavity:
 - 50% to 60% or greater of minor salivary gland tumors are malignant.
- Although any type of salivary gland neoplasm may occur in major and minor salivary glands, a number of salivary gland neoplasms predilect to major glands or to minor glands, including:
 - Predilection to major glands:
 - Warthin tumor (parotid gland)
 - Basal cell adenoma (parotid gland)
 - Oncocytoma (parotid gland)
 - Acinic cell carcinoma (parotid gland)
 - Mammary analogue secretory carcinoma (parotid gland)
 - Basal cell adenocarcinoma (parotid gland)
 - Epithelial-myoepithelial carcinoma (parotid gland)
 - Carcinoma ex pleomorphic adenoma (parotid gland)
 - Salivary duct carcinoma (parotid gland)
 - Oncocytic carcinoma (parotid gland)
 - Others
 - Predilection to minor glands:
 - Canalicular adenoma (lip)
 - Cystadenoma (oral cavity)
 - Polymorphous low-grade adenocarcinoma (palate)
 - Clear cell carcinomas (oral)
 - Cribriform adenocarcinoma of minor salivary glands (base of tongue, oral)
- Major and minor salivary gland neoplasms share similar morphologic features but contrast in other ways that must be considered in their frozen section evaluation:
 - Majority of major salivary gland neoplasms are encapsulated, in part or completely:
 - Major salivary gland benign neoplasms are circumscribed to encapsulated, lacking invasive growth and cytomorphologic features of malignancy:
 - Some benign neoplasms may be multinodular with nodules separate from one another (e.g., pleomorphic adenoma, basal cell adenoma, canalicular adenoma, Warthin tumor).
 - Some benign neoplasms may include foci within soft tissues, in particular recurrent pleomorphic adenomas.
 - Major salivary gland malignant neoplasms show cytomorphologic features of malignancy and/or invasive growth:
 - Cytomorphologically bland-appearing neoplasms may be malignant on the basis of infiltrative growth:
 - ◻ Examples include adenoid cystic carcinoma, basal cell adenocarcinoma, epithelial-myoepithelial carcinoma, others.
 - Noninvasive neoplasms may be malignant on the basis of identifying specific cell types or the presence of anaplastic cellular features:
 - ◻ Examples of neoplasms with specific cell types diagnostic for malignancy include mucoepidermoid carcinoma, acinic cell carcinoma, others.
 - ◻ Examples of neoplasms with anaplastic cellular features diagnostic for malignancy

Fig. 21-1. Configuration of benign and malignant salivary gland neoplasms.

Schematic representation of the gross appearance of the configurations of benign (**A** through **C**) and malignant (**D** through **F**) salivary gland neoplasms. The peripheral appearance of benign salivary gland neoplasms is often (**A**) encapsulated to circumscribed with smooth contours; (**B**) lobulated, as may be seen in pleomorphic adenomas; (**C**) multinodular or multifocal, including satellite nodules, as may be seen in pleomorphic adenoma (de novo or recurrent) or monomorphic adenomas, including but not limited to basal cell adenoma, membranous type, or canalicular adenoma. The peripheral appearance of malignant salivary gland neoplasms often includes infiltrative pattern of growth with varying appearances as depicted in **D** through **F**. Ultimately, histologic confirmation of invasion is required and in the presence of invasion the neoplasm is malignant. (Adapted from Ranchod M, Chan JKC, Eisele DW: *Salivary glands*. In Ranchod M, editor: *Intraoperative consultation in surgical pathology*, New York, 2010, Cambridge University Press.)

Fig. 21-2. Appropriate sectioning of salivary gland neoplasms.

Schematic representation of proper sampling of salivary gland neoplasms. Whether a given tumor has the peripheral appearance of (**A**) benignancy (smooth contour) or (**B**) malignancy (infiltrative pattern), sectioning as depicted in the illustration should include the interface between the tumor, its periphery, and the surrounding normal tissue. (Adapted from Ranchod M, Chan JKC, Eisele DW: *Salivary glands*. In Ranchod M, editor: *Intraoperative consultation in surgical pathology*, New York, 2010, Cambridge University Press.)

Fig. 21-3. Chronic sialadenitis.

Intraoperative consultation, chronic sialadenitis, parotid gland. **A**, At low magnification the normal lobular architecture of the parotid gland is preserved.

B, Inflammatory cell infiltrate including a lymphoid aggregate with edema, fibrosis, scattered identifiable ducts, and acinar cell atrophy. **C**, Higher magnification shows areas with preservation of parenchymal components with associated lymphoid cell infiltrate.

Fig. 21-4. Pleomorphic adenoma.

Intraoperative consultation, pleomorphic adenoma, parotid gland. **A**, Encapsulated tumor separated from adjacent parotid gland (*left*) composed of an admixture of epithelial and chondromyxoid-appearing stroma. **B**, Combination of epithelial cells (glands), myoepithelial cells (spindle and plasmacytoid cells), and chondromyxoid stroma.

include all salivary gland neoplasms composed of histologically high-grade cytomorphology, including salivary duct carcinoma, high-grade carcinoma ex pleomorphic adenoma, high-grade adenocarcinoma, not otherwise specified and high-grade transformation (“dedifferentiation”) of lower grade salivary gland neoplasms.

- All minor salivary gland neoplasms are unencapsulated:
 - Benign minor salivary gland neoplasms are circumscribed without invasive growth.
 - Benign minor salivary gland neoplasms may be multinodular with nodules separate from

Fig. 21-5. Cellular pleomorphic adenoma.

Intraoperative consultation, cellular pleomorphic adenoma, parotid gland. **A**, This was an encapsulated cellular tumor in which residual foci of chondromyxoid stroma was present (*bottom*). **B**, At higher magnification the cellular components include epithelial (glands) and myoepithelial (plasmacytoid) cells.

- one another (e.g., pleomorphic adenoma, basal cell adenoma, canalicular adenoma).
- Some benign neoplasms may include foci within soft tissues, in particular recurrent pleomorphic adenomas.
- Minor salivary gland malignant neoplasms show cytomorphic features of malignancy and/or invasive growth.
- Cytomorphologically bland-appearing neoplasms may be malignant on the basis of infiltrative growth:
 - Examples include adenoid cystic carcinoma, polymorphous low-grade adenocarcinoma, clear cell carcinomas, others.

Fig. 21-6. Myoepithelial-predominant PA.

Intraoperative consultation, myoepithelial-predominant pleomorphic adenoma (PA), palate. **A**, Cellular mass that was circumscribed but unencapsulated; residual areas of chondromyxoid stroma (not shown) were present. **B**, Plasmacytoid myoepithelial cells. **C**, Spindle-shaped myoepithelial cells.

Fig. 21-7. Recurrent pleomorphic adenoma.

Intraoperative consultation, recurrent chondromyxoid-predominant pleomorphic adenoma, parotid gland.

A, Encapsulated tumor separated from adjacent parotid gland (*left*) composed predominantly of chondromyxoid stroma; admixture of epithelial and chondromyxoid-appearing stroma. **B,** Scattered cellular components within the dominant chondromyxoid stroma include epithelial (glands) and myoepithelial (spindle-shaped) cells. **C,** At higher magnification spindle-shaped myoepithelial cells are seen.

Fig. 21-8. Intraoperative consultation, Warthin tumor, parotid gland.

Classic combination of papillary and cystic growth with dense lymphoid cell infiltrate and oncocytic epithelial cells.

- Noninvasive neoplasms may be malignant on the basis of identifying specific cell types or the presence of anaplastic cellular features:
 - Examples of neoplasms with specific cell types diagnostic for malignancy include mucoepidermoid carcinoma, others.
 - Examples of neoplasms with anaplastic cellular features diagnostic for malignancy include all salivary gland neoplasms composed of histologically high-grade cytormorphology, including salivary duct carcinoma; high-grade carcinoma ex pleomorphic adenoma; high-grade adeno-carcinoma, not otherwise specified and high-grade transformation (“dedifferentiation”) of lower grade salivary gland neoplasms.

Fig. 21-9. Mucoepidermoid carcinoma, low-grade.

Intraoperative consultation, low-grade mucoepidermoid carcinoma, parotid gland. **A**, At low magnification there is an infiltrative parotid tumor composed of cystic and solid foci. **B** and **C**, Solid foci are composed of a combination of epidermoid cells and mucocytes. **D**, Cysts are also lined by an admixture of epidermoid and mucous cells although attenuated (flattened) epithelium is seen lining the cyst at the bottom. Presence of thickened (proliferative) cellular foci with admixture of cell types should allow for discrimination between low-grade mucoepidermoid carcinoma and benign cystic lesions such as salivary duct cyst with squamous and mucous cell metaplasia.

Indications for Intraoperative Consultation in Salivary Gland Neoplasms

Major Glands

- Indications for intraoperative consultation in major salivary gland neoplasms include:
 - To render a diagnosis (determine tumor type), which may include:
 - Cases in which there has been an equivocal or inconclusive diagnosis by fine-needle aspiration biopsy (FNAB) or core biopsy
 - Cases in which a prior diagnostic procedure (e.g., FNAB, biopsy) has not been attempted
 - To evaluate surgical margins of resection for adequacy of resection:
 - May include measuring distance between tumor and surgical margin(s)
 - To determine if lymph node metastases are present:
 - Identification of nodal metastasis may result in more extensive neck dissection.
 - High-grade malignant salivary gland neoplasms have increased incidence of nodal metastasis at presentation, including:
 - High-grade mucoepidermoid carcinoma, salivary duct carcinoma, others

Fig. 21-10. Adenoid cystic carcinoma.

Intraoperative consultation, adenoid cystic carcinoma. **A**, Polymorphic growth, including characteristic cribriform pattern as well as foci showing tubular growth. **B**, Area showing trabecular and canalicular growth patterns. Such findings in intraoral lesions would be reminiscent of canalicular adenoma. **C**, Cribriform areas include pseudocysts filled with mucinous material and surrounded by the dominant abluminal (myoepithelial) cells with small but identifiable true glands (arrows) lined by epithelial cells showing eosinophilic cytoplasm. **D**, Neurotropism would be diagnostic for malignancy that, in combination with cribriform growth and cell types, is diagnostic for adenoid cystic carcinoma.

- To obtain tissue for ancillary studies; examples may include:
 - Lymphoma evaluation
 - Cytogenetic evaluation
 - Less commonly, ultrastructural evaluation

Minor Glands

- Indications for intraoperative consultation in minor salivary gland tumors include:
 - To render a diagnosis (determine tumor type), which may include:
 - Cases in which there has been an equivocal or inconclusive diagnosis by fine-needle aspiration biopsy (FNAB) or core biopsy

- Cases in which a prior diagnostic procedure (e.g., FNAB, biopsy) has not been attempted
- To evaluate surgical margins of resection
- To try to determine the presence of perineural invasion:
 - Involvement of palatine nerves from pterygo-palatine fossa is generally determined pre-operatively by radiographic imaging studies.
- To determine osseous involvement that may necessitate resection of bone (palatine bone or maxilla)
- Usually lymph node dissection is not performed for intraoral minor salivary gland neoplasms

Fig. 21-11. Acinic cell adenocarcinoma.

Intraoperative consultation, acinic cell adenocarcinoma, parotid gland. **A**, Residual parotid gland (*extreme right*) is infiltrated by tumor showing solid, cystic, and papillary architectures. **B**, Microcystic growth composed of a cellular proliferation that includes vacuolated cells; such cells are common in acinic cell carcinoma but not uniquely seen in acinic cell carcinoma. **C**, Diagnostic acinar cells showing intracytoplasmic basophilic granules as well as scattered vacuolated cells.

unless there is preoperative diagnosis of a high-grade malignancy.

- If lymph nodes are excised, then a frozen section may be requested to exclude the presence of metastatic disease.
 - Identification of nodal metastasis may result in more extensive neck dissection.
- To obtain tissue for ancillary studies; examples may include:
 - Lymphoma evaluation
 - Cytogenetic evaluation
 - Less commonly, ultrastructural evaluation

Surgeon's Expectations of the Intraoperative Assessment of Salivary Gland Neoplasms

Major Glands

- Surgeon's expectations at the time of intraoperative consultation include:
 - Distinguish between benign and malignant neoplasms
 - Determine specific type and/or histologic grade of malignancy
 - Assess adequacy of the surgical margins
 - Assess for perineural invasion
- All of the above aid surgeon in deciding extent of surgical resection.

Minor Salivary Gland Tumors

- Surgeon's expectations at the time of intraoperative consultation include:
 - Distinguish between benign and malignant neoplasms
 - Determine specific type and/or histologic grade of malignancy
 - In particular, adenoid cystic carcinoma that may necessitate a wider resection to achieve tumor-free margins
 - Assess adequacy of resection margins and possible extent of disease:
 - Margins for minor salivary gland tumors are similar to those for other mucosal lesions and include the depth and circumferential excision lines.
 - Osseous involvement necessitates resection of the involved bone.
- In the oral cavity, the surgeon must consider the possibility of resecting the lesion with a modest margin.
- Additional surgical treatment can be accomplished immediately if frozen section finding indicates the need.
- As with intraoperative consultation of other body sites, frozen section diagnosis of minor salivary gland

Fig. 21-12. Polymorphous low-grade adenocarcinoma.

Intraoperative consultation, polymorphous low-grade adenocarcinoma of the palate. **A**, Submucosal circumscribed cellular proliferation lying adjacent to seromucous glands and extending to the deep resection margin. **B**, The tumor shows variety of growth patterns, including solid nests, scattered tubules/ducts, and cribriform with a myxoid-appearing stroma; **C**, bland cytology with absence of significant pleomorphism and no mitoses; hyalinized stromal tissue is present. **D**, In its depth the tumor infiltrated soft tissues, including skeletal muscle, indicative of a malignant tumor that, in combination with growth patterns and cytomorphology, is diagnostic for polymorphous low-grade adenocarcinoma.

lesions requires close interaction between the surgeon and the pathologist.

Approach to Handling of Resected Tissue

Major Glands

- Majority of salivary gland tumors are located in parotid gland, in particular the superficial lobe, which is a common specimen at the time of intraoperative consultation, but the following are applicable for handling all specimen types:
 - Orient and ink the specimen.
 - Assess extent and location of tumor.
 - Determine if the tumor is within the confines of the glandular capsule or if it has infiltrated beyond the gland.
 - Assess whether the cut surface (glandular surgical margin) is involved by tumor.
 - Evaluation for facial nerve involvement:
 - Involvement of the facial nerve may be apparent preoperatively; however, facial nerve involvement may not be clinically apparent, which may result in frozen section evaluation for presence of facial nerve invasion.
 - Sampling of the facial nerve for frozen section evaluation usually is a very small tissue fragment and the entire nerve should be embedded for evaluation.

- Parotid “lobes” are only a designation of the portion of the gland that is superficial and deep to the facial nerve; there are no true “lobes” of the parotid gland.

Minor Glands

- Handling of intraoral minor salivary gland lesions is similar to other mucosal-based lesions.
- Careful gross examination of resection specimen is imperative.
- In the evaluation of salivary gland tumors in general the gross inspection of the resection specimen:
 - Should determine what is the relation between the lesion and the adjacent tissues
 - Sections submitted for frozen section should show this relationship.
 - The tissue sample should be taken to include the junction of the tumor and surrounding tissues, not just from the center of the lesion, allowing for evaluation of the relationship of the tumor to surrounding structures.
 - The frozen section should be taken between the tumor and the closest line of excision, which allows for determining how far the tumor is from the surgical resection margin.

For Major and Minor Glands

- Gross appearance (Fig. 21-1):
 - Benign salivary gland neoplasms tend to be circumscribed to encapsulated, lacking invasive growth so that the gross appearance generally shows the presence of smooth-appearing peripheral contours:
 - Periphery in benign neoplasms may vary from smooth to lobulated.
 - One or more separate (satellite) nodules may be present:
 - Each separate nodule has a smooth or lobulated outline.
 - Malignant salivary gland neoplasms tend to have infiltrative margins with irregular peripheral contour(s).
- Tissue sectioning (Fig. 21-2):
 - Most critical portion of any salivary gland neoplasm to sample to try to determine whether the neoplasm is or is not infiltrative is the interface between the tumor and surrounding tissues:
 - Such sampling provides the greatest opportunity to determine invasive growth.
 - Invasion in salivary gland neoplasms includes:
 - Infiltration into residual non-neoplastic salivary gland parenchyma, neurotropism (peri- and/or intraneural), invasion into soft tissues and/or bone, extension beyond the confines of the gland
 - Extension into a capsule is not diagnostic for invasion relative to salivary gland neoplasms.

- Vascular permeation may occur in benign neoplasms (e.g., pleomorphic adenoma), so care must be taken when identifying lymph-vascular invasion that the morphology is not that of a pleomorphic adenoma.

- Other than pleomorphic adenoma, the presence of lymph-vascular invasion generally connotes malignancy.
- There are no specific guidelines to the number of sections to take in any given neoplasm and such a determination should be based on:
 - The specific case
 - Experience of the pathologist
 - Communication with the surgeon
- In general:
 - Benign tumors tend to be well circumscribed and usually grow with a broad-based pushing front.
 - Benign tumors may encircle or displace adjacent normal structures but do not infiltrate these structures.
 - Presence of invasion irrespective of the morphology of the tumor automatically places the tumor in a malignant category.

Diagnostic Considerations

- Multiple growth patterns or polymorphism:
 - Virtually all salivary gland neoplasms show more than one growth pattern, including benign neoplasms and malignant neoplasms:
 - Presence of multiple growth patterns or polymorphic growth does equate to a diagnosis of malignancy:
 - An example of this situation could include a palatal neoplasm with polymorphic growth patterns, raising suspicion for a diagnosis of polymorphous low-grade adenocarcinoma, but pleomorphic adenomas of this (and other) locations also may show polymorphous growth patterns; differentiation in this scenario is predicated on the presence or absence of invasion because both tumors share similar cell types and in the absence of clear-cut invasion (e.g., neurotropism, invasion of bone and soft tissues), a definitive diagnosis cannot and should not be rendered.
 - Specific growth patterns do not necessarily equate to a specific diagnosis:
 - Cribriform growth often associated with adenoid cystic carcinoma may be identified in a variety of other tumor types, including pleomorphic adenoma and basal cell adenoma.
 - Microcystic change can be seen in a variety of lesions/neoplasms (benign and malignant),

and caution should be exercised when identifying microcystic change as it is not diagnostic for any specific lesion or tumor type.

- Caution should be exercised in rendering a diagnosis of malignancy on the basis of growth pattern and should be evaluated in concert with the overall features of the neoplasm.
- Dual cell population:
 - Many benign and malignant salivary gland neoplasms are composed of an admixture of epithelial cells and (modified) myoepithelial/basal cells, including (although not necessarily limited to):
 - Pleomorphic adenoma
 - Basal cell adenoma
 - Adenoid cystic carcinoma
 - Epithelial myoepithelial carcinoma
 - Polymorphous low-grade adenocarcinoma
 - Identification and/or distribution of cell types, in particular myoepithelial/basal cells, does not allow for a specific diagnosis or for discriminating among different neoplasms.
- Neoplasms with clear cells:
 - Presence of cells with clear-appearing cytoplasm may be seen in a wide variety of salivary gland neoplasms, including benign and malignant neoplasms, so identification of clear cells whether in a major gland or minor gland neoplasms is not a pathognomonic finding.
 - Clear cells may be seen focally in many salivary gland neoplasms or may be the predominant/exclusive cell type:
 - Evaluation of the entire tumor is required to determine if there are features that may allow classification into a specific tumor type.
 - Histochemical and immunohistochemical evaluation may be required to further determine the tumor type.
 - Primary salivary gland neoplasms with clear cells (wholly or in part) include:
 - Benign neoplasms:
 - Oncocytoma
 - Myoepithelioma
 - Pleomorphic adenoma
 - Monomorphic adenomas
 - Malignant neoplasms:
 - Epithelial-myoepithelial carcinoma
 - Clear cell carcinoma (hyalinizing and non-hyalinizing)
 - Mucoepidermoid carcinoma
 - Acinic cell carcinoma
 - Mammary analogue secretory carcinoma
- Myoepithelial carcinoma
- Oncocytic carcinoma
- Sebaceous carcinoma
- Metastatic neoplasms with clear cells include:
 - Renal cell carcinoma
 - Malignant melanoma
 - Others
- Odontogenic neoplasms represent another class of neoplasms that may include clear cells (wholly or in part), and a diagnosis of an odontogenic neoplasm with clear cells should be taken into consideration when dealing with an intraoral lesion:
 - Generally related to teeth and/or gnathic bone
 - Preoperative clinical and radiologic correlation should alert the pathologist to the possibility of an odontogenic neoplasm.
 - Close working relationship with the surgeon is imperative.
- Neoplasms with vacuolated cells:
 - Vacuolated cells can be seen in a variety of neoplasms (benign and malignant), including:
 - Pleomorphic adenoma
 - Monomorphic adenomas
 - Acinic cell carcinoma
 - Mammary analogue secretory carcinoma
 - Caution should be exercised in rendering a diagnosis of malignancy when identifying vacuolated cells because they are not diagnostic for any specific tumor type.
- Changes secondary to fine-needle aspiration biopsy (FNAB) or core tissue biopsy:
 - Prior FNAB or biopsy may result in degenerative and reactive changes, creating difficulties in the frozen section (and permanent section) evaluation.
 - Post-FNAB or biopsy degenerative and reactive changes may include:
 - Extensive tumor infarction and/or necrosis
 - Squamous metaplasia
 - Mucous cell metaplasia
 - Such degenerative and reactive changes may result in erroneous diagnosis of a malignant neoplasm, especially low-grade mucoepidermoid carcinoma; in contrast to mucoepidermoid carcinoma:
 - Squamous metaplasia typically includes presence of keratinization and intercellular bridges, features not typically seen in mucoepidermoid carcinoma.
 - Findings, especially metaplastic changes, usually are focal and not spread throughout the neoplasm.
 - Absence of invasive growth

- Close communication with the surgeon, including questioning if the lesion had previously been needled or biopsied, may assist in preventing misdiagnosis.
- Among the more common benign neoplasms that may undergo such degenerative and reactive changes include (but are not limited to):
 - Warthin tumor
 - Pleomorphic adenoma
 - Oncocytoma
- Cystic change:
 - Many salivary gland lesions/neoplasms may be cystic and/or undergo cystic change.
 - Cystic low-grade mucoepidermoid carcinoma may be problematic to differentiate from non-neoplastic cystic lesions (e.g., salivary duct cyst), especially with associated squamous and mucous cell metaplasia.
 - Presence of more solid/cellular foci composed of admixture of mucocytes, epidermoid cells, and intermediate cells supports a diagnosis of mucoepidermoid carcinoma, distinguishing it from salivary duct cyst with squamous and mucous cell metaplasia.
 - Cystic change may be seen and predominate in acinic cell carcinoma, but the identification of characteristic cells with basophilic granular cytoplasm allows for a diagnosis.
- Multifocal neoplasms:
 - Some primary salivary gland neoplasms may be multifocal within a single gland or in multiple (bilateral) glands or may be multinodular, including:
 - Warthin tumor (most common):
 - May be bilateral in approximately 12% of cases
 - Pleomorphic adenoma:
 - De novo or recurrent
 - Monomorphic adenomas:
 - Basal cell adenoma, in particular membranous type
 - Canalicular adenoma
 - Metastatic tumors to salivary glands, a rare occurrence, may be multifocal.
- Metastatic tumors:
 - Rarely, metastatic neoplasms may spread to salivary glands.
 - Usually not an issue for frozen section evaluation as a diagnosis established by fine-needle aspiration biopsy or core biopsy
 - Most metastases to salivary glands occur from primary malignancies in the head and neck, including:
 - Squamous cell carcinoma
 - Malignant melanoma
 - Less commonly, metastatic tumor from a non-head and neck malignancy may occur to salivary glands
 - Most common scenario is widespread metastasis in a patient with known nonsalivary gland primary malignancy.
 - Less often, metastatic tumor may occur from an occult primary malignancy.
 - At frozen section some issues/considerations include:
 - Presence of keratinization and intercellular bridges in a malignant neoplasm that may include mucocytes generally indicative of a squamous cell carcinoma and not mucoepidermoid carcinoma
 - Difficulties in classifying a given tumor within the spectrum of salivary gland tumor classification should raise the possibility of the presence of metastatic disease.

Accuracy of Intraoperative Diagnosis

- Among a variety of studies evaluating accuracy of frozen section diagnosis in large numbers of salivary gland neoplasms, it has been shown that frozen section diagnosis of salivary gland tumors is reliable and clinically valuable, with accuracy rates ranging from 90% to 98%.
 - Reported sensitivity and specificity of a malignant diagnosis include 98.5% and 99.0%, respectively.
- False-positive, false-negative, and deferral rates are reported to be as high as 2%, 12%, and 10%, respectively.
- Sampling errors represent a primary reason for false-negative errors.
- Clinically significant error rates are probably lower than reported because a proportion of these tumor “errors” are classification changes within the same category.
- Accuracy of fine-needle aspiration biopsy (FNAB) versus frozen section include:
 - For FNAB, sensitivity 73%, specificity 87%, positive predictive value 61%, and negative predictive value 90%
 - For frozen section, sensitivity 80%, specificity 98%, positive predictive value 92%, and negative predictive value 94%
 - Meta-analysis studies of frozen section diagnosis of salivary gland neoplasm to be consistently accurate across study centers
- Frozen section pathology for salivary gland lesions, in particular parotid lesions, has high accuracy and utility in intraoperative decision making, facilitating timely complete procedures.

BIOPSY DIAGNOSIS OF SALIVARY GLAND NEOPLASMS (Figs. 21-13 through 21-18)

- Initial diagnostic modality for a patient with a salivary gland mass often includes fine-needle aspiration biopsy (FNAB) or incisional biopsy.
- Biopsy sampling of salivary gland neoplasms frequently consists of lesional material without surrounding tissues:
 - In such a scenario:
 - Differentiation neoplasms with overlapping histologic features, including growth patterns and bland cytomorphology, may be problematic.
 - Sole determinant may be presence or absence of invasive growth that in presence of only lesional tissue without surrounding tissues on biopsy precludes assessment of relationship of neoplasm to surrounding tissues and may not allow for definitive diagnosis:
 - S100 protein may be of assistance in trying to identify neurotropism.
 - ◻ Absence of neurotropism does not exclude a diagnosis of malignancy.
- ◻ Many neoplasms included in this specific differential diagnosis (see below) have lesional cells that are S100 protein positive:
 - Utility of S100 protein is in trying to identify presence of perineural invasion because it is not specific to any single salivary gland neoplasm
- Among more common benign and malignant (major or minor) salivary gland neoplasms that may create problems in a definitive diagnosis and ability to differentiate one from another include:
 - Pleomorphic adenoma (PA), “usual” and cellular types
 - Basal cell adenoma (BCA)
 - Basal cell adenocarcinoma (BCAdC)
 - Adenoid cystic carcinoma (AdCC)
 - Polymorphous low-grade adenocarcinoma (PLGA)
- Shared pathologic features of above neoplasms may include:
 - Growth patterns:
 - All salivary gland neoplasms are characterized by more than one growth pattern, so presence of polymorphous growth is not a definitive diagnostic finding for malignancy:
 - Polymorphism does not equate to polymorphous low-grade adenocarcinoma.

Fig. 21-13. Incisional biopsy of oral cavity submucosal lesion.

A, Biopsy includes tissue fragment entirely composed of lesion (*left*) and adjacent hyalinized tissue, the latter is part of the lesion rather than representing surrounding nonlesional tissue. **B**, Higher magnification shows solid and tubular growth (polymorphism) composed of bland-appearing basaloid cells with hyperchromatic nuclei without significant nuclear pleomorphism or increased mitotic activity. Immunohistochemical staining (not shown) included reactivity with cytokeratins and myoepithelial markers. The overall biopsy findings could be those of a cellular pleomorphic adenoma, basal cell adenoma, or a low-grade carcinoma. A diagnosis of “salivary gland neoplasm, not further specified” was rendered with the recommendation for conservative but complete excision. Following complete excision, the tumor was not invasive with findings diagnostic for basal cell adenoma.

Fig. 21-14. Overlapping features in benign and malignant salivary gland neoplasms.

Shared histologic findings that can be seen in benign and malignant salivary gland neoplasms include **(A)** tubular growth with myxoid-appearing stroma and bland cytologic features; **(B)** tubular and solid growth composed of basaloid nuclei lacking significant nuclear pleomorphism and increased mitotic activity; **(C)** cribriform growth; **(D)** hyalinized and myxoid stroma surrounding lesion with solid and focally glandular growth composed of bland-appearing cells with basaloid nuclei. Although these examples may suggest a specific diagnosis, in the absence of surrounding tissues to evaluate for the presence (or absence) of invasive growth an unequivocal diagnosis cannot be rendered and a diagnosis of “salivary gland neoplasm, not further specified” may be prudent with a recommendation for conservative but complete resection.

- No single growth pattern or combination of growth patterns defines any specific neoplasm or distinguishes among salivary gland neoplasms.
- Specific patterns may suggest a specific diagnosis:
 - Cribriform growth characteristically associated with adenoid cystic carcinoma but may be seen in other tumors, including pleomorphic adenoma and basal cell adenoma
 - Nuclear palisading of basaloid cells along the stromal interface is often seen in BCA and BCAdC but is not specifically diagnostic.
 - Presence of squamous differentiation a feature seen in BCA and BCAdC can be seen in PA and PLGA but generally not in AdCC.
 - Swirling or whorling patterns often at lesion’s periphery characteristic, although not pathognomonic for polymorphous low-grade adenocarcinoma
 - Single filing of tumor cells (akin to lobular carcinoma of the breast) another characteristic (although not pathognomonic) finding associated with polymorphous low-grade adenocarcinoma

Fig. 21-15. Diagnostic findings for malignancy in salivary gland neoplasms.

Definitive diagnostic findings for a salivary gland carcinoma in incisional biopsies may include cell types and invasive growth: **(A)** cell types diagnostic for mucoepidermoid carcinoma include an admixture of mucocytes, epidermoid cells, and intermediate cells; **(B)** cell type diagnostic for acinic cell carcinoma includes presence of cells with basophilic granular cytoplasm confirmed by **(C)** presence of DOG-1 immunoreactivity (apical, cytoplasmic, and membranous); invasive growth includes **(D and E)** invasion into skeletal muscle (**D** representing adenoid cystic carcinoma; **E** representing polymorphous low-grade adenocarcinoma).

Fig. 21-16. Perineural invasion.

Neurotropism in biopsies of salivary gland neoplasms is diagnostic for carcinoma. The following examples are from separate cases of polymorphous low-grade adenocarcinoma. **A**, Readily apparent peri- and intraneural invasion seen on light microscopic evaluation. **B**, Although unnecessary given the light microscopic findings, S100 protein highlights the nerve surrounded and infiltrated by neoplastic cells which are also S100 protein positive. **C**, Incisional biopsy of a palate lesion with a submucosal neoplastic proliferation showing **(D)** more subtle (*arrow*) and potentially overlooked perineural invasion. **E**, S100 protein highlights the small nerve (*arrow*) surrounded by neoplastic cells, which are also S100 protein positive.

Fig. 21-17. Acinic cell adenocarcinoma vs mammary analogue secretory carcinoma.

Needle biopsy of submandibular gland tumor diagnostic for carcinoma. **A** and **B**, Limited biopsy material that at low magnification shows a neoplastic proliferation with papillary, hobnail, and solid growth. **C**, At higher magnification vacuolated cells and cells with vague-appearing intracytoplasmic granules are present. **D**, A smear of the tumor prepared during the biopsy procedure showed the presence of cells with vacuolated-appearing cytoplasm (*arrowheads*). The overall findings are most suggestive for either an acinic cell carcinoma or mammary analogue secretory carcinoma. Immunohistochemical staining showed the lesional cells to be reactive for **(E)** mammaglobin, **(F)** S100 protein, and

**Fig. 21-17, cont'd**

(G) GATA-3 but negative for (H) DOG-1. The findings are diagnostic for mammary analogue secretory carcinoma.

- Despite purportedly specific growth patterns, PA, BCA, BCAdC, PLGA, and AdCC share too many architectural features to permit definitive diagnosis based on any single or combination of growth patterns.
- Limited sampling may not be representative of entire neoplasm, and more definitive diagnostic features not seen in biopsy material may be present only with availability of entire neoplasm following complete resection:
 - Features suggestive of benign neoplasm on biopsy (e.g., PA or BCA) may prove to be malignant based on invasive growth (e.g., perineural invasion) only seen following complete resection, providing availability of entire tumor and surrounding tissues; conversely, features suggestive of malignant neoplasm on biopsy (e.g., PLGA, AdCC) may prove to be benign only following complete resection with absence of invasive growth
- Cytomorphologic findings:
 - PA, BCA, AdCC, PLGA, and BCAdC may share bland cytomorphologic findings, including limited nuclear pleomorphism and absent to rare mitotic figures
- Dual cell population:
 - Many salivary gland neoplasms, especially more common ones, including PA, BCA, AdCC, PLGA, BCAdC, are composed of epithelial cells and myoepithelial cells, so identification of both cell types by light microscopy and/or immunohistochemical staining does not allow for their differentiation.
- Tumor stroma:
 - Chondromyxoid stroma represents a histologic component of PA
 - Even in limited quantity, chondromyxoid stroma facilitates distinction of pleomorphic adenoma from basal cell adenoma
 - Chondromyxoid stroma derives from neoplastic (modified) myoepithelial cells and often includes myoepithelial cells “streaming” through the matrix.
 - Due to limitations of tissue sampling, the chondromyxoid stroma of pleomorphic adenoma may not be present in an incisional biopsy specimen.
 - Absence of chondromyxoid stroma does not preclude a diagnosis of pleomorphic adenoma nor should absence of chondromyxoid stroma prompt a diagnosis of basal cell adenoma
 - Hyalinized (collagenized) stroma:
 - Can be seen in PA, BCA (membranous subtype), BCAdC, and AdCC:
 - Sometimes show small “droplets” of matrix within nests of neoplastic cells, whereas AdCC exhibits a combination of mucoid basophilic pseudocysts and hyaline eosinophilic pseudocysts.
 - Stromal features are potentially useful within the appropriate context, but definitive diagnosis of salivary gland tumors generally depends upon additional considerations.
- Mitotic activity and proliferation indices:
 - PA, BCA, PLGA, AdCC, and BCAdC are frequently devoid of mitotic activity, although for benign and malignant neoplasms scattered mitotic figures may be identified.
 - Malignant neoplasm sometimes shows increased mitotic activity, including atypical mitoses, but mitotic figures do not distinguish

Fig. 21-18.

Needle biopsy of parotid gland tumor diagnostic for carcinoma. **A**, Small tissue fragment showing a densely cellular proliferation (*arrowhead*) with scattered cells within fibroconnective tissue (*arrows*). **B** and **C**, Neoplastic cells in densely cellular area (**B**) and less cellular area (**C**) show moderate to marked nuclear pleomorphism with hyperchromatic nuclei. On the basis of the cytomorphic features, the findings are those of a malignant undifferentiated neoplasm. Immunohistochemical staining showed the lesional cells to be reactive for (**D**) cytokeratin (AE1/AE3); (**E**) androgen receptor (nuclear); (**F**) GATA-3 (nuclear). The findings are diagnostic for salivary duct carcinoma (either occurring *de novo* or possibly the malignant component of a carcinoma ex pleomorphic adenoma). Radical excision of the tumor and neck dissection were subsequently performed confirming a diagnosis of a (*de novo*) salivary duct carcinoma with nodal metastasis.

- malignant lesions from their benign counterparts.
- Although there may be slightly higher proliferation indices in malignant neoplasm as determined by Ki67 (MIB1) immunoreactivity, proliferation indices do not definitively distinguish low-grade malignant salivary gland neoplasm from benign salivary gland neoplasm.
 - Immunohistochemical findings:
 - PA, BCA, BCAdC, AdCC, and PLGA share many similar immunohistochemical findings (Table 21-1) to allow for differentiation solely based on their immunohistochemical staining characteristics.
 - Unique staining patterns have been suggested as allowing for discriminating among salivary gland neoplasms:
 - C-kit (CD117) has been investigated as a potential marker of AdCC, in particular the intensity of C-kit staining of luminal cells in AdCC, but c-kit expression is not unique to AdCC, as this marker may be seen in other salivary gland neoplasms, including PLGA, PA, and BCA.
 - Pairing p63 and p40 reported to assist in differentiating PA from PLGA and AdCC:
 - PA: p63+, p40+; discordant p63+/p40– staining pattern identified in overtly mesenchymal-rich chondromyxoid stroma
 - PLGA: consistent p63+ and p40–
 - AdCC: p63+ and p40+:
 - Although p63/p40 immunohistochemical pairing can be a valuable tool for differentiating PA, PLGA, and AdCC, it is not infallible, and any given example may demonstrate divergence from reported p63/p40 immunophenotype.
 - When can a definitive diagnosis be established in incisional biopsy (or FNAB)?
 - Identification of specific cell types diagnostic for specific neoplasms:
 - Admixture of epidermoid cells, mucocytes, and intermediate cells:
 - Support diagnosis of MEC but caution should be exercised as metaplastic changes, including squamous metaplasia and mucous cell metaplasia, can be seen in benign neoplasms, including PA and Warthin tumor

TABLE 21-1 Immunohistochemistry* of Selective Salivary Gland Neoplasms

Tumor	PanK	LMWK	HMWK	p63	p40	S100	DOG-1	MGB	AR	GATA-3	Her-2	CD117	PLAG1
PA	+	+	+	+	+	+	–	–	–	v	–	v	+
BCA/BCAdC	+	+	+	+	+	+	–	–	–	v	–	v	v
MYO	+	+	+	+	+	+	–	–	–	v	–	v	+
MEC	+	+	+	+	+	–	–	–	–	v	–	v	–
ACC	+	+	+	–	–	–	+	–	–	–	–	–	–
MASC	+	+	+	–	–	+	–	+	–	+ (n)	–	–	–
AdCC	+	+	+	+	+	+	+ [†]	–	–	–	–	+ (lum)	–
PLGA	+	+	+	+	–	+	–	–	–	–	–	v	v
SDC	+	+	+	–	–	–	–	–	+ (n)	+ (n)	v (memb)	–	–
EMC	+	+	+	+	+	+	+ [†]	–	–	–	–	–	–
CCC/HCCC	+/+	+/+	+/+	–/+	–	–/–	–/–	–/–	–/–	–/–	–/–	–/–	–/–

*Staining characteristics vary widely among tumor types and even within the same tumor type. This table details ideal staining characteristics per tumor type, and although these staining patterns generally remain consistent, any given tumor listed may defy “convention” and show reactivity for a marker usually not associated with that tumor or may lack a marker usually associated with that tumor (e.g., p63 in myoepithelial cells).

†Frequently positive, often showing distinctive combined apical ductal and membranous/cytoplasmic myoepithelial staining profile.

ACC, Acinic cell carcinoma; AdCC, adenoid cystic carcinoma; AR, androgen receptor; BCA, basal cell adenoma; BCAdC, basal cell adenocarcinoma; CCC, clear cell carcinoma, including hyalinizing type; DOG-1, discovered on GIST1; EMC, epithelial-myoepithelial carcinoma; GATA-3, GATA binding protein 3; HCCC, hyalinizing clear cell carcinoma; HMWK, high molecular weight cytokeratin (e.g., CK5/6, CK14); LMWK, low molecular weight cytokeratin (e.g., CK7, CK8, CK19); lum, strong staining luminal cells; MASC, mammary analogue secretory carcinoma; MEC, mucoepidermoid carcinoma; memb, membranous; MGB, mammaglobin; MYO, myoepithelioma; n, nuclear; PA, pleomorphic adenoma; PanK, pancytokeratin (e.g., AE1/AE3; CAM5.2); PLAG1, pleomorphic adenoma gene 1; PLGA, polymorphous low-grade adenocarcinoma; SDC, salivary duct carcinoma; V, variably positive.

Specific staining characteristics:

DOG1: should be admixture of strong apical membranous, cytoplasmic and complete membranous staining

Mammaglobin: should be strong and diffuse cytoplasmic staining in MASC (same for S100 protein in this tumor)

PLAG1 immunohistochemical staining may not be confirmed by FISH analysis even for PA.

- Neoplastic acinar cells:
 - In presence of a mass, especially of parotid gland including cells with prominent intracytoplasmic basophilic granules, a diagnosis of acinic cell carcinoma can be rendered, especially when coupled with DOG-1 immunoreactivity:
 - DOG-1 immunoreactivity in ACC includes complex mixture of intense (3+) apical membranous, cytoplasmic, and complete membranous staining; strong staining used to support diagnosis of acinic cell carcinoma
 - Other tumor types that may express DOG-1 include adenoid cystic carcinoma and epithelial-myoepithelial carcinoma, showing distinctive combined apical ductal and membranous/cytoplasmic myoepithelial staining profile but lack intensity associated with ACC.
- Vacuolated cells:
 - Not pathognomonic for any neoplasm but often identified in acinic cell carcinoma, mammary analogue secretory carcinoma (MASC), and mucoepidermoid carcinoma (MEC):
 - Vacuolated cells with DOG-1 reactivity, absence of mammaglobin and GATA-3 reactivity, and absent or weak focal S100 protein reactivity supports diagnosis of acinic cell carcinoma
 - Vacuolated cells with strong mammaglobin, S100 protein, and GATA-3 (nuclear) reactivity and absent DOG-1 reactivity support diagnosis of MASC.
- Clear cells:
 - Not uniquely diagnostic for any specific salivary gland neoplasm as may be seen in a wide variety of tumor types, including benign and malignant neoplasms
 - Immunohistochemical staining may assist in trying to determine nature of neoplasm.
 - Unique *EWSR1* translocation seen in hyalinizing clear cell carcinoma and some clear cell myoepithelial carcinomas but limited tissue sampling may preclude cytogenetic evaluation
- Presence of cytomorphologically high-grade features:
 - Support diagnosis of malignancy, which would be sufficient to plan for definitive treatment (e.g., radical extirpation, neck dissection):
 - In general treatment for all high-grade salivary gland carcinomas is similar irrespective of specific tumor type
 - Definitive diagnosis can be suggested in conjunction with certain immunohistochemical findings:
 - Neoplasm with cytomorphologically high-grade nuclear features (with or without increased mitotic activity and necrosis) coupled to diffuse and strong immunoreactivity for androgen receptor (with or without HER-2 staining) and GATA-3 supports diagnosis of salivary duct carcinoma (SDC), which in turn may be a:
 - De novo SDC
 - Malignant component in carcinoma ex pleomorphic adenoma
 - In presence of cells/nuclei with high-grade features, confirmation of epithelial origin achieved with cytokeratin staining:
 - Absence of reactivity with epithelial markers may suggest malignant lymphoma, latter confirmed by presence of reactivity with hematolymphoid markers (e.g., CD45, CD20, others)
 - Attention to nuclear chromatin may suggest presence of neuroendocrine differentiation that can be confirmed by presence of reactivity for neuroendocrine-related markers (e.g., synaptophysin, chromogranin); within group of neuroendocrine carcinomas of salivary gland origin, diagnosis of Merkel cell type can be confirmed by presence of immunoreactivity for CK20 and Merkel cell polyomavirus (MCPyV)
 - Generally, treatment for all high-grade salivary gland malignant neoplasms is similar, including radical surgical excision plus neck dissection so that a diagnosis of “high-grade carcinoma” irrespective of more specific classification will prompt similar therapeutic approach.
- Presence of invasive growth:
 - Invasion of residual nonlesional salivary gland parenchyma:
 - Perineural/intraneural invasion:
 - Either by light microscopy and/or use of S100 protein to highlight nerve surrounded/infiltrated by tumor confers a diagnosis of malignancy (i.e., carcinoma) but may not differentiate among tumor types:
 - Overlapping features shared by such neoplasm as AdCC, PLGA, and BCAdC
 - Angioinvasion or lymph-vascular invasion
 - Invasion of other soft tissue structures, including:
 - Skeletal muscle
 - Bone

TABLE 21-2 Salivary Gland Neoplasms: Chromosomal Translocations

Tumor	Chromosomal Translocation	Gene Fusion	Percentage of Cases
Pleomorphic adenoma	Rearrangement of 8q12: t(3;8)(p21;112) t(5;8)(p13;q12) Rearrangement of 12q13-15: t(3;12)(p14.2;q14-5) ins(9;12)(p23;q12-15)	<i>PLAG1</i> <i>HMGA2</i>	Approximately 70%
Mucoepidermoid carcinoma	t(11;19)(q21;p13) t(11;15)(q21;q26)	<i>CRTC1-MAML2</i> <i>CRTC3-MAML2</i>	60%-80% 6% or less
Adenoid cystic carcinoma	t(6;9)(q22-23;p23-24)	<i>MYB-NFIB</i>	80%-90%
Mammary analogue secretory carcinoma	t(12;15)(p13q25)	<i>ETV6-NTKR3</i>	Translocation 80% ETV6 break 99%
Hyalinizing clear cell carcinoma (HCCC) Clear cell variant of myoepithelial carcinoma (CCMC) [†]	t(12;22)(q13;q12)	<i>EWSR1-ATF1</i>	For HCCC 80% For CCMC 39% [†]

Epithelial-myoepithelial carcinoma	No translocation but a mutation	<i>HRAS</i> exon3, codon 61	27%*

*Chiosea SI, Miller M, Seethala RR: *HRAS* mutations in epithelial-myoepithelial carcinoma, Head Neck Pathol 8:146-150, 2014.

[†]Includes de novo CCMC and CCMC ex pleomorphic adenoma. From Skalova A, Weinrib I, Hycza M, et al: Clear cell myoepithelial carcinoma of salivary glands showing EWSR1 rearrangement, Am J Surg Pathol 39:338-348, 2015.

- Noted caveats to above findings include:
 - In general, presence of neurotropism and invasion of residual salivary gland parenchyma are diagnostic for malignancy:
 - Relative to salivary gland neoplasms, benign neoplasms are not neurotropic and do not invade (efface) non-neoplastic salivary gland tissues.
 - Occasionally, benign neoplasms may permeate into lymph-vascular spaces:
 - Noted example would be pleomorphic adenoma
 - Occasionally, benign neoplasms may be identified within soft tissues, including skeletal muscle (but not usually bone):
 - Noted example would be recurrent pleomorphic adenoma (chondromyxoid predominant or usual type)

Conclusions

- In summary, FNAB and incisional biopsy diagnosis of salivary gland lesions, including major glands and minor glands (e.g., intraoral), can be difficult to differentiate a benign from malignant neoplasm, especially histologically low-grade carcinomas, including

adenoid cystic carcinoma and polymorphous low-grade adenocarcinoma:

- Often biopsy material is too limited to allow for differentiation given absence of surrounding tissues to evaluate for presence of infiltrative growth.
- Overlapping immunohistochemical findings, including reactivity with epithelial and myoepithelial markers:
 - S100 protein may be most useful stain in trying to establish presence of neurotropism that, if found, would be diagnostic for carcinoma, although differentiation among low-grade carcinomas may still be problematic.
- Presence of specific chromosomal translocation/gene fusion linked to specific neoplasms and would allow for specific diagnosis when identified (Table 21-2), but limited sampling in FNAB or incisional biopsy may not yield sufficient material to perform molecular analysis
- Treatment for benign neoplasms (e.g., PA, BCA) and low-grade salivary gland carcinomas generally similar, including complete resection to include tumor-free margins without sacrifice of nerves and without neck dissection in absence of clinical evidence of neck disease

- In absence of definitive diagnostic findings, better to render a diagnosis of “salivary gland neoplasm, not further specified” with recommendation for complete resection, including tumor-free margins
 - Neoplasms appearing benign on FNAB/biopsy may prove malignant following complete resection.
 - Neoplasms appearing malignant on FNAB/biopsy may prove benign following complete resection.
- Following complete resection and availability of entire neoplasm for histologic evaluation, a definitive diagnosis can be established, and any adjunct therapy, if needed, can be instituted.

Embryology, Anatomy, Histology, and Physiology of the Thyroid Gland

EMBRYOLOGY OF THE THYROID (Fig. 26-1)

- Thyroid gland is the first endocrine gland to appear during embryonic development.
- Thyroid gland derives from three primordium, median anlage, and lateral anlagen:
 - Median anlage develops around the twenty-fourth day of gestation as a small, median endodermal thickening on primitive pharynx.
 - This thickening forms a diverticulum, which attaches to tongue by a narrow tube referred to as thyroglossal duct.
 - Opening in base of tongue constitutes foramen cecum
 - Lateral anlagen correspond to ultimobranchial body, which derives from pharyngeal pouches:
 - Ultimobranchial body from which C-cells originate fuses and incorporates into thyroid gland.
- As result of further cellular proliferations, hollow thyroid diverticulum obliterates and divides into right and left lobes, connected by isthmus around seventh week of gestation.
- During development thyroid descends and assumes a definitive position in anterior neck, at which time:
 - Thyroglossal duct undergoes atrophy
 - In approximately 40% to 50% of individuals, inferior end of thyroglossal duct persists as pyramidal lobe, which is attached to hyoid bone by fibrous or muscular tissue.
 - Faulty migration (of medial anlage) or persistence of thyroglossal duct may give rise to thyroid ectopia (e.g., lingual thyroid, other) or thyroglossal duct cysts.
- Proximal opening persists as foramen cecum of tongue.
- Development of thyroid gland controlled by coordinated action of specific transcription factors, including:
 - Thyroid transcription factor 1 (TTF-1), TTF-2, paired box gene 8 (PAX8), and hematopoietically expressed homeobox (HHEX)
 - Altered expression of transcription factors play a role in thyroid dysgenesis.
- Thyroid follicular cells:
 - Endodermal cell mass constituting thyroid primordium is separated into cords by invasion of vascular mesenchyme and divide into smaller groups around tenth week of gestation.
 - A single layer of cells becomes arranged around a lumen, and primitive follicles make their appearance around the eleventh week of gestation.
 - At the time colloid is stored, iodine concentrates and hormone synthesis can be demonstrated.
 - By week 14, follicles with central lumen containing colloid are well developed.
 - Follicular cells and colloid are thyroglobulin positive.
- Thyroid C-cells:
 - Neuroendocrine cells presumed to be of neural crest derivation
 - Originate from ultimobranchial body that migrates into pharyngeal pouches from branchial arches:
 - Reach thyroid via ultimobranchial body, which originates from fourth and fifth branchial pouch complex
 - While still attached to pharynx, ultimobranchial bodies start migration downward on each side of neck together with parathyroid fourth anlage.
 - At 7 to 8 weeks, ultimobranchial bodies separate from pharynx and parathyroids.
 - At weeks 8 to 9 appear as solid masses fusing with dorsolateral aspects of median thyroid anlage incorporated into developing lateral thyroid lobes
 - C-cells are largely restricted to middle and upper thirds of lateral thyroid lobes.
 - C-cells produce calcitonin, which regulates normal calcium levels in body.
 - Solid cell nests are believed to be remnants of ultimobranchial body

ANATOMY OF THE THYROID (Fig. 26-2)

- Thyroid gland is a reddish tan organ located in lower part of the neck on either side of the larynx and trachea placed anteriorly at level of fifth cervical to first thoracic vertebrae.
- Thyroid gland is ensheathed by pretracheal layer of deep cervical fascia consisting of right and left lobes

Fig. 26-1. Development of the thyroid gland.

A and B, Schematic sagittal sections of the head and neck regions of embryos at 5 and 6 weeks, illustrating successive stages in the development of the thyroid gland. **C,** Similar section of an adult head and neck showing the path taken by the gland during its embryonic descent (indicated by the former tract of the thyroglossal duct). (From Moore KL, Persaud TVN, Torchia M: *The developing human: clinically oriented embryology*, ed 10, Philadelphia, 2015, Elsevier.)

connected by a narrow median band of tissue referred to as the isthmus, which overlies the three tracheal rings below cricoid cartilage.

- Weight of thyroid gland varies from 15 to 25 g in adults, is heavier in women than in men, and varies during pregnancy, iodine intake, and other pathologic conditions.
- Lateral thyroid lobes have a conical shape, measuring 5 cm long, 3 cm transversally, and 2 cm anteroposteriorly:

- Their ascending apices diverge laterally to level of oblique lines on laminae of thyroid cartilage, and their bases are level with fourth and fifth tracheal rings.
- Each lobe, in posteromedial aspect, is attached to side of cricoid cartilage by a lateral thyroid ligament.
- Isthmus connects both lobes, measures 1.25 cm transversely and vertically, and extends anterior to the second and third tracheal rings.
- Pyramidal thyroid lobe:
 - Present in approximately 40% to 50% of the population
 - Conical shaped, projecting upwards from isthmus ascending to hyoid bone
 - Appears generally as a fibrous tract, but in pathologic conditions becomes prominent or cystic
- Thyroid gland capsule:
 - Thyroid gland invested by thin connective tissue capsule firmly attached to gland
 - Numerous fibrous septa penetrate thyroid parenchyma, dividing gland into lobules.
 - Although gland grossly may appear completely encapsulated, microscopically capsule is incomplete in majority of population.
- Surfaces and relations:
 - Convex lateral (superficial) surface of thyroid gland is covered by sternothyroid muscle.
 - Medial surface is adapted to larynx and trachea.
 - Superior pole contacts inferior pharyngeal constrictor and posterior part of cricothyroid, which separate it from posterior part of thyroid lamina and side of cricoid cartilage.
 - Inferiorly, trachea and more posteriorly recurrent laryngeal nerve (running in the tracheoesophageal space) and esophagus (closer on the left side) are medial relations.
 - Posterolateral surface of thyroid gland is close to carotid sheath and overlaps common carotid artery.
 - Anterior border is thin and near anterior branch of superior thyroid artery it slants down medially.
 - Rounded posterior border is related inferiorly to inferior thyroid artery and its anastomosis with posterior branch of superior thyroid artery.
 - On left side, lower end of posterior border of thyroid lies near thoracic duct.
 - Parathyroid glands are usually related to posterior border.
 - Isthmus is covered by sternothyroid muscle from which it is separated by pretracheal fascia; more superficially isthmus is covered by sternohyoid muscle, anterior jugular veins, fascia, and skin.

Fig. 26-2. Anatomy of the thyroid gland.

A, Frontal view drawing of the neck with the chin raised shows the typical location of the thyroid gland in relationship to the larynx and trachea. **B**, Frontal drawing of the thyroid gland showing the position of the gland relative to the trachea and larynx. Also shown is a pyramidal lobe and the musculus levator glandulae thyroideae. (A, Modified from www.netterimages.com. B, Modified from Sobota Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Vascular Supply and Lymphatics of the Thyroid

Arteries and Veins

- Thyroid gland is a richly vascularized organ with vascular supply derived from superior and inferior thyroid arteries:
 - Arteries are large and branches anastomose frequently on and in thyroid gland ipsilaterally and contralaterally.
 - Arteria thyroidea ima from brachiocephalic trunk or aortic arch sometimes provides vascular supply.
- Superior thyroid artery:
 - Arises from external carotid artery and is closely related to external branch of superior laryngeal nerve; descends forward and downward to superior pole of the thyroid gland, pierces thyroid fascia, and divides into anterior and posterior branches
 - Anterior branch supplies anterior surface, runs down over anterior surface of thyroid gland to isthmus, and anastomoses with superior thyroid artery of contralateral side.
 - (Smaller) posterior branch supplies lateral and medial surface, courses posterolateral surface of gland and through small ramus communicans, and anastomoses with inferior thyroid artery from same side.
- Inferior thyroid artery:
 - Larger than superior thyroid artery originates from thyrocervical trunk, branch of the subclavian artery, passes behind and close to carotid sheath and under common carotid artery, approaches base of thyroid gland, and divides into superior (ascending) and inferior branches at level of junction of inferior and middle thirds of thyroid gland to supply inferior and posterior surfaces of thyroid gland:
 - Superior branch also supplies parathyroid glands.
 - Relationship of inferior thyroid artery and recurrent laryngeal nerve is highly variable and of clinical importance as iatrogenic injury to nerves supplying larynx is a potential major complication of thyroid surgery.
 - Recurrent laryngeal nerve usually related to posterior branch of inferior thyroid artery
- In thyroid gland arteries penetrate substance and divide into numerous branches throughout parenchyma, giving origin to a rich capillary network that ends in capillaries around follicles.
- Venous drainage of thyroid gland usually via superior, middle, and inferior thyroid veins:
 - Superior thyroid vein emerges from upper part of gland, runs with superior thyroid artery towards carotid sheath, and drains into internal jugular vein.
 - Middle thyroid vein collects blood from lower part of gland, emerges from lateral surface of gland, and drains into internal jugular vein.
 - Inferior thyroid vein arises in glandular venous plexus, which also connects with middle and superior thyroid veins.

- Efferent vessels anastomose frequently and accompany arteries to surface of gland, forming a large venous (pretracheal) plexus in fascia covering gland from which:
 - Left inferior vein descends to join left brachiocephalic vein and right descends obliquely across brachiocephalic artery to join right brachiocephalic vein at its junction with superior vena cava.
 - Inferior thyroid vein often opens via a common trunk into superior vena cava or left brachiocephalic vein.
- Thyroid lymphatics may drain directly with no intervening node to thoracic duct.
- Thyroid endowed with rich lymphatic network that may not be readily evident in hematoxylin and eosin staining requiring immunostaining with podoplanin (D2-40) for identification
- Regional lymph nodes include: (Fig. 26-3)
 - Pericapsular lymph nodes:
 - Intraglandular lymph vessels penetrate capsule merging with pericapsular lymph nodes to form plexus around thyroid gland.
 - Pretracheal, paratracheal, and prelaryngeal lymph nodes:
 - Drain inferior portion of gland
 - Prelaryngeal lymph node referred to as Delphian node:
 - Along with para- and pretracheal make up level VI
 - Lies adjacent to thyroid gland once regarded as sentinel for thyroid disease and drains thyroid gland and larynx lying anterior to cricothyroid ligament
 - Enlargement may be indicative of metastasis from thyroid or laryngeal carcinoma.
 - Name originates from Oracle of Delphi, whose prophecy in this case would be unpleasant death secondary to laryngeal cancer
 - Internal jugular chain lymph nodes:
 - Includes subdigastic nodes
 - Collecting lymph vessels draining superior portion of thyroid lobes and isthmus

Lymphatics

Fig. 26-3. Regional lymph nodes of the thyroid gland.

Frontal view of the thyroid gland shows its vascular supply. Also shown are the primary drainage lymph nodes of the thyroid gland. Not shown are the level I and retropharyngeal nodes. (Modified from www.netterimages.com.)

- Recurrent laryngeal nerve chain lymph nodes
- Retropharyngeal and retroesophageal lymph nodes
- Drainage from thyroid gland may also include anterosuperior mediastinal lymph nodes.

Nerves

- Thyroid gland receives innervation from superior, middle, and inferior cervical sympathetic ganglia.
- In thyroid gland through perivascular and interfollicular plexus, nerves end near follicular basement membrane, influencing thyroid secretion indirectly by action in blood vessels.
- Small paraganglia normally present close to thyroid and occasionally found beneath thyroid capsule

HISTOLOGY (Fig. 26-4)

- Thyroid gland capsule:
 - A thin fibrous capsule completely envelops thyroid gland with septa that divide thyroid gland incompletely into lobules:
 - Capsule includes sizable vascular spaces as well as small peripheral nerves and is continuous with pretracheal fascia.
 - In practice, a fibrous capsule of thyroid gland is often not identifiable by microscopic examination.
 - Criteria for defining (minimal) extrathyroidal extension may be problematic and subjective; see later in Chapter 28 for more detailed discussion.
- Thyroid gland is divided by connective tissue septae into lobules, each one of these containing from 20 to 40 follicles:
 - Each follicle is considered a functional unit of thyroid gland.
- Thyroid follicular epithelial cells:
 - Thyroid follicles consist of rounded structures of variable size lined by a single layer of flattened (inactive) to cuboidal or rarely columnar (cylindrical) cells and a lumen containing a proteinaceous colloid material representing storage product of secretory activity of follicular cells:
 - Cuboidal cells are most numerous and major function is to secrete colloid.
 - Single follicle may have flattened cells on one side and cuboidal cells on other side.
 - Follicular cells have a central rounded or ovoid nucleus with delicate chromatin, a single (eccentric) nucleolus, and an eosinophilic or amphophilic cytoplasm:
 - Nuclear chromatin is coarse, appearing finely granular or clumped.
 - Uncommonly normal follicular cells may have deeply eosinophilic cytoplasm referred to as oncocytes (so-called Hürthle cells).
 - Lipofuscin appearing as an intracytoplasmic golden brown pigment may be present.
- Follicles are separated by loose fibroconnective tissue.
- Follicles have an average diameter of 200 microns.
 - Size varies according functional status of gland or patient age.
- Follicles are surrounded by a basement membrane:
 - Remain in close relationship with lymphatics, a rich capillary network, and nerves present around individual follicles
- Colloid is:
 - Pale eosinophilic with scalloped borders in actively secreting gland and deeply eosinophilic in resting follicles
 - Variably periodic acid Schiff (PAS) and alcian blue positive
 - Calcium oxalate crystals may be visualized in colloid in normal and pathologic conditions.
- Immunohistochemistry: follicular cells are immunoreactive for:
 - Thyroglobulin (intraluminal colloid is also reactive):
 - Dedicated and specific marker of thyroid follicular cells including tumors of thyroid follicular cell origin:
 - Represents single best marker for determination of thyroid follicular cell origin
 - Follicular cells with cytoplasmic oncocytic change (so-called Hürthle cells) show much lesser degree of thyroglobulin reactivity.
 - Tends to leak out from cytoplasm of follicular cells and may diffuse into cytoplasm of other (nonfollicular) cells, including non-thyroid tumors potentially resulting in diagnostic misinterpretation
 - Thyroid transcription factor 1 (TTF-1) (nuclear staining):
 - Homeodomain transcription factor expressed in thyroid, diencephalon, and lung
 - Necessary in thyroid organogenesis and differentiation:
 - Regulates expression of thyroid peroxidase (TPO) and thyroglobulin genes
 - Extremely useful marker for thyroid follicular cells, including tumors of thyroid follicular cell origin but unlike thyroglobulin may be reactive in other tumor types, including tumors of thyroid C-cell origin (i.e., medullary thyroid carcinoma)
 - Reactive in a broad spectrum of tissue types and tumors, therefore not as dedicated and

Fig. 26-4. Normal thyroid follicular epithelial cells.

A, Thyroid gland lobule containing numerous colloid-filled follicles; each follicle is considered a functional unit of thyroid gland. **B**, Variable-sized colloid-filled follicles lined by single layer of flattened (inactive) to cuboidal follicular cells with round or ovoid nuclei and coarse nuclear chromatin. Immunohistochemical staining of follicular cells includes reactivity for **(C)** thyroglobulin (colloid is also immunoreactive), **(D)** thyroid transcription factor 1 (TTF-1; nuclear staining), **(E)** PAX8 (nuclear staining), and **(F)** CD56 (membranous staining).

- specific as thyroglobulin relative to thyroid follicular cells and lesions/tumors derived from follicular cells
- Paired box gene 8 (*PAX8*) (nuclear staining):
 - Member of Pax family of transcription factors defined by common element, the Paired (Prd) domain, by which they bind to specific DNA sequences
 - *PAX8* gene located on human chromosome 2q12-q14
 - Along with TTF-1 (and TTF-2) necessary in thyroid organogenesis and differentiation
 - CD56 (membranous staining):
 - May be present in thyroid follicular cells and lesions/tumors of follicular cell origin
 - Low molecular weight keratins:
 - CK7, CK18, CK8, CK19
 - Epithelial membrane antigen
 - Vimentin
 - Galectins:
 - Implicated in cell growth and differentiation, intercellular recognition, and adhesion
 - Galectin-3 (GAL-3) stains normal follicular cells and carcinomas
 - Estrogen and progesterone receptors may be identified.
 - Laminin and type IV collagen stain basement membrane of the follicles.
 - Electron microscopy:
 - Numerous microvilli are seen in the luminal surface of the follicular cells.
 - Cells are joined tight junctions containing occludin and various claudins.
 - Cytoplasm has abundant rough endoplasmic reticulum, a well-developed Golgi apparatus in a supranuclear or paranuclear position, and lysosomes in the apical cytoplasm.
 - Thyroid C-cells (parafollicular cells) (Fig. 26-5)
 - Represent a second population of distinct cells in thyroid gland
 - Have neuroendocrine function responsible for production of calcitonin
 - Are encountered at junction of upper third and middle thirds of lateral thyroid lobes:
 - Tend to aggregate in vicinity of solid cell nests
 - Not present in isthmus portion of gland
 - Are difficult to identify in routine stain sections but can be recognized due to their location in follicles and their morphologic characteristics:
 - Located individually or in small groups within thyroid follicles:
 - Found at periphery of follicular wall within its basement membrane without contact with follicular lumen
 - Ultrastructurally C-cells occupy an intrafollicular position separated from thyroid interstitium by follicular basal lamina
 - Are round, polyhedral, or spindle shaped with round to oval nuclei and granular weakly eosinophilic to clear cytoplasm and are larger and paler than follicular cells
 - Number of C-cells varies from neonatal period to adulthood:
 - Numerous cells found at birth to single cells or smaller groups in adult thyroid parenchyma
 - Histochemistry:
 - C-cells can be selectively stained by silver techniques, including:
 - Grimelius (argyrophilic) stain, Churukian-Schenk, and the silver nitrate of Cajal revealing brown to black cytoplasmic granules
 - Immunohistochemistry: C-cells are immunoreactive for:
 - Calcitonin (cytoplasmic staining)
 - Calcitonin-gene-related peptide (CGRP)
 - Cytokeratins:
 - Pankeratins, CK7
 - Neuroendocrine markers, including synaptophysin, chromogranin
 - Thyroid transcription factor-1 (TTF-1) (nuclear stain)
 - Carcinoembryonic antigen (CEA)
 - CD56, CD57
 - Neuron-specific enolase
 - Somatostatin and serotonin
 - Electron microscopy:
 - Characteristic of C-cells is presence of round electron dense membrane bound neuroendocrine-type granules, which range in size from 60 to 550 nm in diameter:
 - 2 types of granules identified, including type I and type II
 - Most C-cells have type I rather than type II secretory granules.
 - C-cells are enclosed in the basement membrane of follicular cells without reaching the lumen of the follicles due to interposition of follicular cells.
 - Solid cell nests (SCN):
 - Consist of collection of cells with a squamoid appearance lacking intercellular bridges, most probably representing remnant of ultimobranchial body from which the C-cells originate; see Chapter 27 for discussion

Thyroid Stroma

- Thyroid stroma includes:
 - Blood vessels
 - Lymphatics
 - Fibrous tissue
- Lymphocytes are not normally a component of thyroid stroma and presence of lymphocytes is

Fig. 26-5. Normal thyroid C-cells.

A, C-cells identified in between follicles (*arrows*) and associated with thyroid follicular cells (*arrowhead*) in a para-follicular location without contact with follicular lumen. **B**, Another example of para-follicular location of C-cells (*arrowheads*). Note in both images the C-cells are larger with more dispersed-appearing nuclear chromatin as compared to follicular epithelial cells. Immunohistochemical staining of C-cells includes reactivity for **(C)** calcitonin, **(D)** synaptophysin, **(E)** TTF-1 (nuclear staining) present in C-cells and follicular epithelial cells but **(F)** negative for thyroglobulin staining (*arrowheads*), which is reactive in the follicular epithelial cells.

abnormal; see Chapter 27 for discussion of lymphocytic infiltrates in thyroid gland parenchyma.

- Typically, normal thyroid gland is devoid of mature adipose tissue and skeletal muscle but either or both of these mesenchymal tissues can be found in thyroid gland as anatomic variation or metaplasia; see Chapter 27 for discussion of fat and muscle in thyroid gland parenchyma.

PHYSIOLOGY

- Main function of thyroid gland is production of thyroid hormones, including:
 - Thyroxine (T_4)
 - Triiodothyronine (T_3)
- Thyroid hormones regulate metabolism, increase protein synthesis throughout the body, and increase oxygen consumption:
 - Also important for body development and normal maturation of central and peripheral nervous systems
- Thyroid hormones:
 - Are stored in thyroglobulin
 - Stimulate metabolism, increase oxygen consumption, and cause a rise in heart production, cardiac output and heart rate
 - Essential for normal development, growth, and maturation
- Thyroid biosynthetic and secretory activities controlled by blood level of thyroid-stimulating hormone (TSH), a glycoprotein secreted by anterior pituitary gland:
 - TSH release regulated thyrotropin-releasing hormone (TRH), a tripeptide secreted by hypothalamus
 - TSH and TRH release regulated by circulating levels of T_3 and T_4 via negative feedback on pituitary and hypothalamus:
 - Low levels of T_3 and T_4 stimulate release of TSH and TRH.
 - High levels of T_3 and T_4 inhibit release of TSH and TRH.
 - Prolonged high levels of circulating TSH induce follicular cell hypertrophy, progressive resorption of colloid, and increased stromal vascularity.
- Exogenous iodine required for synthesis of T_4 :
 - Iodine balance maintained by dietary sources
 - Many conditions modify iodine intake, including medications, dietary supplements, and food additives.
- Calcitonin:
 - 32 amino acid peptide
 - Secretion regulated primarily by extracellular calcium concentration
 - Main function is regulation of level of calcium in plasma by feedback mechanism via inhibition of osteoblastic activity:
 - Increase in serum calcium concentration above normal physiologic levels activates calcium-sensing receptor, a G-protein coupled receptor that facilitates increased calcitonin secretion from the thyroid gland
 - Binding of calcitonin to its receptor on osteoclast inhibits bone resorption, lowering blood calcium by inhibiting bone resorption and calcium recovery from renal tubule ultrafiltrate
 - Resulting reduction in calcium concentration leads to lower calcitonin secretion.
 - Other stimuli enhancing calcitonin secretion include supraphysiologic concentrations of glucagon, gastrin (and pentagastrin), and cholecystokinin.

Embryology, Anatomy, and Histology of the Ear

EMBRYOLOGY

External Ear

- External ear develops from the first brachial groove.
- Auricle (pinna) develops from the auricular hillocks, a group of six mesenchymal swellings, from the first and second branchial arches lying around the first branchial groove.
- Mesenchymal structures of the auricle arise from the mesoderm of the first and second branchial arches.
- Epithelium of the external auditory canal develops from the ectoderm at the dorsal end of the first branchial groove or cleft.
- Tympanic membrane forms from the first and second branchial pouches and the first branchial groove:
 - Ectoderm of the first branchial groove gives rise to the epithelium on the external side.
 - Endoderm from the first branchial pouch gives rise to the epithelium on the internal side.
 - Mesoderm of the first and second branchial arches gives rise to the connective tissue lying between the external and internal epithelial surfaces.

Middle Ear

- Middle ear space develops from invagination of the first branchial pouch (pharyngotympanic tube) from the primitive pharynx.
- Endoderm of the tubotympanic recess, a derivative of the first pharyngeal pouch, gives rise from its distal portion to the epithelium of the tympanic cavity and the mastoid antrum, and from its proximal portion to the epithelium of the auditory tube (eustachian or pharyngotympanic tube).
- Middle ear ossicles have different derivations:
 - Malleus and incus develop from the mesoderm of the first branchial arch cartilage (Meckel cartilage).
 - Stapes develops from the mesoderm of the second branchial arch cartilage (Reichert cartilage).
- Tensor tympani muscle, attached to the malleus, derives from the first branchial arch; stapedius muscle attached to the stapes, derives from the second branchial arch.

Inner Ear

- First of the three anatomic divisions of the ear to develop beginning toward the end of the first month of gestation.
- Membranous labyrinth, including the utricle, saccule, semicircular ducts, and cochlear duct, arises from the otic vesicle (otocyst), an invagination from the surface ectoderm, which migrates into its position, losing its connection to the surface ectoderm.
- Otic vesicle forms from the invagination of the surface ectoderm, located on either side of the neural plate, into the mesenchyme:
 - Invagination eventually loses its connection with the surface ectoderm.
- Bony labyrinth including the vestibule, semicircular canals, and cochlea arises from the mesenchyme around the otic vesicle.

ANATOMY (Figs. 22-1 through 22-3)

- The ear can be considered as three distinct regions or compartments to include:
 - External ear
 - Middle ear and temporal bone
 - Inner ear

External Ear

- Consists of the auricle (pinna), external auditory canal (or meatus), and the tympanic membrane at the medial end of the auditory canal.
- Outer portion of the external ear includes the auricle or pinna leading into the external auditory canal:
 - Skeleton of the auricle consists of a single plate of elastic cartilage conforming to the shape of the ear.
 - Lobule is the only part of the auricle that is devoid of skeletal support.
 - Cartilage of the auricle is continuous with that of the external auditory canal.
- External auditory canal or meatus extends from the concha to its medial limit, which is the external aspect of the tympanic membrane:
 - Lateral portion of external canal wall consists of cartilage and connective tissue.

- Medial portion of external canal wall consists of bone.
- Cartilaginous part of the external auditory canal constitutes slightly less than half its total length.
- Inconstant fissures referred to as the fissures of Santorini occur in the cartilage; these fissures may

Fig. 22-1. Anatomy of the external ear.

- transmit infection from the canal to the parotid gland and superficial mastoid regions, or vice versa.
- Bony part of the canal is formed by both the tympanic part and the petrous part of the temporal bone.
- In adults, anterior and inferior walls of the cartilaginous canal are closely related to the parotid gland.
- Anterior wall of the bony canal is closely related to the mandibular condyle, the posterior wall to the mastoid air cells, and the medial portion of the superior wall to the epitympanic recess.
- Tympanic membrane (eardrum) is situated obliquely at the end of the external auditory canal sloping medially from above downward and from behind forward:
 - Tympanic membrane is a fibrous sheet interposed between the external auditory canal and the middle ear cavity.
 - Connective tissue interposed between these two layers consists of radiating fibers attached to the manubrium of the malleus that are reinforced peripherally by circular fibers
 - In the upper portion of the tympanic membrane there is a limited area where the connective tissue

Fig. 22-2. Anatomy of the middle ear and temporal bone.

Fig. 22-3. External (lateral) aspect of the tympanic membrane (eardrum).

(Modified from Mills, Stacy E: *Histology for pathologists*, ed 3, Philadelphia, 2007, Lippincott, Williams, and Wilkins, Fig. 14-5.)

fibers are lacking; this area is referred to as the pars flaccida or Shrapnell membrane. In this area the tympanic portion of the temporal bone is deficient; this gap is referred to as the tympanic incisure or the notch of Rivinus, where the tympanic membrane attaches to the temporal bone.

- Remainder of the tympanic membrane in which there are intact connective tissue fibers is referred to as the pars tensa.
- Outer aspect of the tympanic membrane is concave:
 - Center of the concavity is referred to as the umbo, which is the strong point of attachment of the manubrium of the malleus to the tympanic membrane.
 - In otoscopic examinations of the tympanic membrane, the bright area of light reflection present downward and forward from the umbo is referred to as the “cone of light.”

Borders

- Medial border:
 - Limited medially by the external aspect of the tympanic membrane

Middle Ear (Tympanic Cavity)

- Middle ear or tympanic cavity lies within the temporal bone between the tympanic membrane and the squamous portions of the temporal bone laterally and the petrous portion of the temporal bone surrounding the inner ear medially.
- Contents include:
 - Ossicles (malleus, incus, and stapes), ligaments of the ossicles, tendons of the ossicular muscles,

eustachian tube, tympanic cavity proper, epitympanic recess, mastoid cavity, and the chorda tympani of the facial (VII) nerve

Eustachian (Auditory) Tube

- Extends from its tympanic ostium high on the anterior wall of the tympanic cavity to a nasopharyngeal ostium situated posterior to the inferior nasal concha.
- Can be divided into an osseous portion and cartilaginous portion:
 - Osseous portion or canal has a bony wall and is the lateral or tympanic third of the tube.
 - Anteromedial two thirds has a cartilaginous and connective tissue wall and is referred to as the cartilaginous portion of the tube.
 - Cartilaginous and osseous tubes meet at an obtuse angle.
- Eustachian tube is not straight but slightly S-shaped:
 - In adults:
 - Tympanic ostium is approximately 2 to 2.5 cm higher than is the nasopharyngeal end and runs downward, medially, and anteriorly to the nasopharynx.
 - Length of the tube in adults varies from 31 to 38 mm.
 - In infants:
 - Tube is shorter, relatively wider, and more horizontal in its course and therefore an easier pathway for infections ascending from the nasopharynx to the tympanic cavity.

Borders

- Lateral (internal) border:
 - Internal aspect of the tympanic membrane and squamous portion of the temporal bone
- Medial border:
 - Petrous portion of the temporal bone
- Superior border (roof):
 - Delimited by the tegmen tympani, a thin plate of bone that separates the middle ear space from the cranial cavity
- Inferior (floor):
 - Thin plate of bone separating the tympanic cavity from the superior bulb of the internal jugular vein
- Anterior border:
 - Delimited by the thin plate of bone separating the tympanic cavity from the carotid canal housing the internal carotid artery
- Posterior border:
 - Petrous portion of the temporal bone containing the mastoid antrum and mastoid air cells
- Tympanic cavity communicates anteriorly with the nasopharynx by way of the eustachian (auditory or pharyngotympanic) tube and communicates posteriorly with the mastoid air cells by way of the aditus and mastoid antrum.

Function

- Middle ear as well as the external ear function as conduits for sound conduction for the auditory part of the internal ear.

Inner Ear (Labyrinth)

- Embedded within the petrous portion of the temporal bone and composes the medial portion of the temporal bone adjacent to the cranial cavity
- Consists of the structures of the membranous (otic) labyrinth that is surrounded by an osseous layer or bony shell termed the osseous (bony) labyrinth (otic capsule), and the internal auditory canal in which the vestibulocochlear nerve (VIII) runs

Function

- Membranous labyrinth contains the cochlea, which is the organ of hearing and the vestibular system, which is the system of balance (equilibrium).
- Complexity of the anatomy of the inner ear is beyond the scope of this book, and the reader is referred to specific texts for more details.

INNERVATION**External Ear**

- Overlapping innervation including auriculotemporal branch of the mandibular branch of trigeminal (V) nerve; cutaneous branches of the cervical plexus, primarily the greater auricular and lesser occipital nerves from C2 and C3; and the auricular branches of the vagus (X) (nerve of Arnold), glossopharyngeal (IX), and facial (VII) nerves
- External aspect of the tympanic membrane is innervated from the auriculotemporal branch of cranial nerve V and the auricular branches of cranial nerves X, IX, and VII.

Middle Ear

- Nerve supply is chiefly from the tympanic plexus formed by the tympanic branch of the glossopharyngeal nerve (nerve of Jacobson) and from the carotico-tympanic nerves derived from the internal carotid plexus.

Inner Ear

- Nerve to the inner ear is the vestibulocochlear nerve or the eighth cranial nerve; these nerves run together in the internal auditory canal until the lateral end, at which point they separate into three parts, two vestibular and one cochlear.
- Fibers of the vestibular nerve arise from Scarpa ganglion.

BLOOD SUPPLY AND LYMPHATIC DRAINAGE**External Ear**

- Arteries and veins:
 - Blood supply to the auricle comes from branches of the external carotid artery.
 - Blood supply to the external auditory canal is the same as that to the auricle and in addition receives blood from the deep auricular artery, a branch of the internal maxillary artery.
 - Veins from the auricle and external auditory canal are the superficial temporal and posterior auricular veins, which join with the jugular veins and sometimes to the sigmoid sinus.
- Lymphatics:
 - From the auricle and external auditory canal to the parotid lymph nodes, the superficial cervical nodes, and the retroauricular lymph nodes

Middle Ear

- Arteries and veins:
 - Arterial supply to the middle ear is mostly derived from branches of the external carotid artery, including the internal maxillary, posterior auricular, and ascending pharyngeal arteries.
 - Veins of the middle ear parallel those of the arteries and empty into the pterygoid venous plexus and the superior petrosal sinus.
- Lymphatics:
 - To the retropharyngeal and parotid lymph nodes

Inner Ear

- Arteries and veins:
 - Primary arterial supply to the internal ear is via the labyrinthine or internal auditory artery, a branch of the anterior inferior cerebellar artery, or from the basilar artery.
 - Veins parallel those of the arteries and empty into the superior petrosal sinus or the transverse sinus.
- Lymphatics:
 - Internal ear is not usually described.

HISTOLOGY**External Ear (Fig. 22-4)**

- Auricle is essentially a cutaneous structure composed of keratinizing, stratified squamous epithelium with associated adnexal structures including hair follicles, sebaceous glands, and eccrine sweat glands; its subcutaneous tissue is composed of fibroconnective

Fig. 22-4. Histology of external auditory canal.

A, The external ear is a cutaneous structure composed of keratinizing stratified squamous epithelium with associated adnexal structures including hair follicles, sebaceous glands, and eccrine sweat glands; keratinizing squamous epithelium lines the entire external auditory canal and covers the external aspect of the tympanic membrane. **B**, The outer third of the external canal includes the presence of ceruminous glands (modified apocrine glands), which are submucosal in location, arranged in clusters or lobules, and composed of a two-cell layer, including the inner or secretory cells containing intracytoplasmic cerumen appearing as granular, golden-yellow pigmentation, and flattened-appearing myoepithelial cells located peripheral to the secretory cells; the secretory cells show holocrine (decapitation) type secretion.

- tissue, fat, and elastic-type fibrocartilage, which gives the auricle its structural support.
- Outer third of the external canal is noteworthy, in addition to the other adnexal structures, for the presence of modified apocrine glands called ceruminous glands, replacing the eccrine glands seen in the auricle:
 - Ceruminous glands:
 - Produce cerumen
 - Are submucosal and arranged in clusters
 - Are composed of two cell layers:
 - Inner or secretory cells appear cuboidal with eosinophilic cytoplasm often containing intracytoplasmic granular, golden-yellow pigment (cerumen); secretory cells show holocrine (decapitation) type secretion characterized by secretory droplets along their luminal border.
 - Myoepithelial cells lie peripheral to the secretory cells and appear as flattened cells.
 - Ducts of the ceruminous glands terminate in the hair follicle or on the skin.
 - Ducts of ceruminous glands lack apocrine or myoepithelial cells.
 - In the inner portion of the external auditory canal, ceruminous glands, as well as the other adnexal structures, are absent.
 - Like the auricle, the external auditory canal is lined by keratinizing squamous epithelium, which runs throughout the canal and covers the external aspect of the tympanic membrane.
 - Tympanic membrane has a central bilaminated zone, including lateral radially arranged and medial circularly arranged collagenous fibers.
 - Inner two thirds of the external auditory canal contains bone instead of cartilage.
 - Due to the absence of adnexal structures there is relatively close apposition of the epithelium to the subjacent bone.

Auditory Epithelial Migration

- Represents the mechanism by which keratin is removed from the tympanic membrane; without such a self-cleaning process the keratin squames normally produced by the stratified squamous epithelium of the tympanic membrane would continuously build up and interfere with the conduction of sound via the tympanic membrane.
- Entire epithelium including keratin moves from the tympanic membrane onto the deep external auditory canal; from the deep external auditory canal the epithelium moves laterally to the junction of the deep (osseous) canal and the cartilaginous canal, where it is desquamated.
- Auditory epithelial migration occurs in two separate and discrete pathways:
 - Epithelium moves upward over the handle of the malleus then moves posterosuperiorly across the pars flaccida moving laterally over the deep canal.
 - Other pathway is radially moving centrifugally away from the handle of the malleus and pars

Fig. 22-5. Histology of tympanic membrane.

A, The tympanic membrane is covered externally by keratinizing squamous epithelium and **B**, internally (middle ear or tympanic cavity side) by a single layer of flattened cuboidal epithelium. The presence of chronic inflammatory cells between the two types of epithelium represents a component of chronic otitis media. The tympanic cavity, including mastoid air cells (not shown), is also lined by cuboidal epithelium.

flaccida to the periphery of the tympanic membrane and then to the deep canal.

- Process of auditory epithelial migration has been felt to represent a possible pathogenesis for the development of cholesteatoma; however, there is no definitive evidence linking auditory epithelial migration to the development of cholesteatoma.

Middle Ear (Figs. 22-5 and 22-6)

- Epithelial lining of the tympanic cavity, including internal aspect of the tympanic membrane (i.e., eardrum) is composed of:

Fig. 22-6. Histology of eustachian tube.

A, The eustachian tube is lined by ciliated pseudostratified columnar epithelium. The presence of lymphoid aggregates, in particular in children, may become hyperplastic, closing off the eustachian tube and providing a milieu for otitis media. **B**, In the cartilaginous portion of the eustachian tube (*bottom right*) seromucinous glands can be identified lying immediately below the ciliated pseudostratified columnar epithelium.

- Single flat layer of cuboidal epithelium lining the tympanic cavity and mastoid
- Low ciliated epithelium from much of its length of the eustachian tube except as it approaches its nasopharyngeal end, where it becomes ciliated pseudostratified columnar epithelium containing goblet cells
- Epithelial lining the eustachian tube becomes pseudostratified as it approaches the pharyngeal end.

- Under normal conditions, there are no glandular elements within the middle ear; the presence of glandular epithelium in the middle ear is abnormal (e.g., metaplastic in otitis media, middle ear adenoma).
- Ciliated pseudostratified columnar epithelium may be found in limited patches among the flattened or cuboidal epithelium.
- Eustachian tubes contain:
 - A lymphoid component, particularly in children, referred to as Gerlach's tubal tonsil:
 - Reactive hyperplasia of this lymphoid component particularly in children may close off the eustachian tube, providing a milieu for otitis media.
 - Seromucinous glands in its cartilaginous portion
- Persistence of cartilage in each of the ossicles and the bifurcation of the stapes to form the crura with the obturator foramen between them distinguishes the middle ear ossicles from other long bones.
- Head of the stapes is formed of endochondral bone with a cartilaginous cap at the incudostapedial joint.
- Crura of the stapes are formed of periosteal bone only.
- From the middle ear aspect of the stapes footplate to its vestibular surface the histologic findings include the flattened to cuboidal epithelium of the tympanic cavity, a thin layer of bone, cartilage, and a single flattened (perilymphatic) epithelial cell layer.
- Malleus and incus, similar to long bones, have an outer covering of periosteal bone layer and an inner core of endochondral bone with well-formed haversian systems:
 - Manubrium (handle) of the malleus is covered predominantly by retained cartilage instead of periosteal bone.
 - Entire inner core of the manubrium, as well as the rest of the malleus, is composed of endochondral bone.
 - Short process of the incus shows a tip of unossified cartilage.

Mastoid Air Cells

- Represent a network of intercommunicating spaces that emanate from the tympanic cavity
- Each air cell is lined by flattened to cuboidal epithelium, which rests on periosteum that covers a thin frame of lamellar bone.

Pneumatization of the Temporal Bone

- In the newborn the rudimentary mastoid bone contains a single air space, the antrum, surrounded by diploic bone containing hematopoietic elements.
- As the mastoid process develops, the marrow spaces hollow out.
- Mesenchymal component occupying the space is resorbed and the developing air-containing cells become lined by the advancing endodermal epithelium.
- Mastoid process is constantly pneumatized in adults, although not in the infant:
 - Cells grow out from the antrum, as well as from each other, forming complex interlocking chains of thin-walled cavities opening into each other.
 - Antrum apparently always has air cells; the mastoid process is usually one of several types including pneumatized (containing air cells), diploic (containing marrow), mixed (containing air cells and marrow), or sclerotic.
 - Approximately 80% of people the mastoid is well pneumatized by the age of 3 or 4, but in approximately 20% of people normal pneumatization fails to occur.

Middle Ear Ossicles

- Middle ear ossicles develop from cartilage with a single center of ossification for bone; there is no epiphyseal ossification.

Middle Ear Joints

- Both the incudomalleal and incudostapedial joints are diarthrodial.
- Ossicular articulations are typical synovial joints.
- Middle ear epithelium is present on the outer surface of the joint capsule and synovial membrane is present on its inner surface.
- Joint capsule is composed of fibrous tissue with a high elastic fiber content.
- Articular disk representing the space in between the articular ends is composed predominantly of fibrocartilage.
- Articular processes of the malleus and the incus are covered by cartilage.

Inner Ear

- Complexity of the anatomy of the inner ear is beyond the scope of this book, and the reader is referred to specific texts for more details.

Non-Neoplastic Diseases of the Ear

CLASSIFICATION OF NON-NEOPLASTIC LESIONS OF THE EAR

BOX 23-1 Classification of Non-Neoplastic Lesions of the Ear and Temporal Bone

External Ear

- Developmental (accessory tragi; first branchial cleft anomalies, others)
- Infectious and inflammatory
- Keloid
- Epidermal and sebaceous cysts
- Idiopathic cystic chondromalacia
- Chondrodermatitis nodularis helices chronicus
- Autoimmune systemic diseases:
 - Relapsing polychondritis
 - Gout
 - Granulomatosis with polyangiitis (formerly Wegener granulomatosis)
 - Others

- Exostosis
- Synovial chondromatosis

Middle and Inner Ear Including Temporal Bone

- Developmental and congenital anomalies
- Infectious (otitis media) and inflammatory
- Otic or aural polyp
- Cholesteatoma
- Langerhans cell histiocytosis
- Heterotopias (central nervous system tissue; salivary gland)
- Otosclerosis
- Paget disease
- Ménière disease
- Others

CONGENITAL AND DEVELOPMENTAL ABNORMALITIES OF THE EAR

- The ear, including the external, middle, and internal ear, often is the target organ for congenital anomalies.
- Congenital abnormalities occur as an isolated defect or in combination with other aural and extra-aural abnormalities and vary from cosmetic defects to complete hearing loss.
- A complete discussion of the developmental defects of the ear is beyond the scope of this chapter; the interested reader is referred to other texts that detail this subject.
- This section includes the more common developmental abnormalities that the surgical pathologist is likely to be confronted with in daily practice.

- Located on the skin surface often anterior to the auricle and may clinically be mistaken for a papilloma
- Thought to be related to second branchial arch anomalies
- May occur independent of other congenital anomalies but may occur in association with cleft palate or lip, mandibular hypoplasia, or in association with other anomalies such as Goldenhar syndrome (oculoauriculovertebral dysplasia)

Pathology

- Histologically, accessory tragi recapitulate the normal external auricle and include skin, cutaneous adnexal structures, and a central core of cartilage.

Differential Diagnosis

- Squamous papilloma:
 - The absence of cutaneous adnexal structures and cartilage differentiates squamous papilloma from accessory tragi.

Treatment and Prognosis

- Simple surgical excision is curative.

EXTERNAL EAR

Accessory Tragi (Figs. 23-1 and 23-2)

Synonyms: Supernumerary ears, accessory auricle, polyotia

Clinical

- Appear at birth
- Unilateral or bilateral, solitary or multiple, sessile or pedunculated, soft or cartilaginous, skin-covered nodules or papules.

Fig. 23-1. Accessory tragus.

Accessory tragus appearing as pedunculated, skin-covered papules located on the skin surface anterior to the auricle; these lesions may be mistaken clinically for a papilloma.

Fig. 23-2. Accessory tragus.

Histologically, accessory tragi recapitulate the normal external auricle as evidenced by the presence of skin, including keratinizing squamous epithelium, cutaneous adnexal structures, and a central core of cartilage.

Branchial Cleft Anomalies

- First branchial cleft anomalies typically occur in the area of the external ear and include cysts, sinuses, and fistulas.
- See the Section on the Neck for more complete discussion.

MIDDLE AND INNER EAR

Developmental Defects

- Numerous developmental or congenital anomalies affect the middle ear and temporal bone; a complete discussion of the developmental defects of the ear is beyond the scope of this chapter. The interested reader is referred to other texts.
- In brief, developmental or congenital anomalies of the middle ear and temporal bone include a variety of anatomic variations and anomalies, hereditary deafness (primarily conductive) occurring in syndromes, deafness caused by noxious prenatal influences, first and second branchial arch syndromes, dysplasias of the osseous and membranous cochlea and vestibular labyrinth, and hereditary/genetic sensorineural hearing loss.
- Other dysplasias of the external, middle, and inner ear include a combination of hypertelorism, microtia, and clefting, and 18q syndrome.
- Anatomic variations and anomalies may involve the facial nerve, jugular bulb, and intratemporal carotid artery:
 - Facial nerve anomalies include congenital bony dehiscence of the facial canal, anatomic variation, or anomalies in the course of the facial nerve, mastoid segment anomalies, anatomic variation of the chorda tympani nerve, and abnormal facial artery and vein.
 - Jugular bulb anomalies include superolateral extension of the bulb or superomedial enlargement of the bulb.
 - Abnormalities of the intratemporal carotid artery include aneurysm, aberrant location, abscess and inflammatory necrosis, traumatic lacerations, and atherosclerotic changes.
- Hereditary deafness primarily conductive occurring in syndromes include:
 - Mandibulofacial dysostosis (Treacher Collins syndrome)
 - Acrofacial dysostosis (Nager syndrome)
 - Craniofacial dysostosis (Crouzon syndrome)
 - Klippel-Feil syndrome (fused vertebra, short neck, facial asymmetry, visceral abnormalities, deafness)
 - Marfan syndrome (arachnodactyly, ectopia lentis, deafness)

- Pierre Robin syndrome (cleft palate, micrognathia, glossoptosis, low-set ears, deformed pinna, and hearing loss)
- Other hereditary diseases causing conductive hearing loss, include osteoporosis (Albers-Schönberg disease or marble bone disease), otosclerosis, osteogenesis imperfecta
- Deafness caused by noxious prenatal influences (embryopathic atresias) include:
 - Maternal rubella
 - Birth injuries
 - Hyperbilirubinemia (erythroblastosis fetalis)
 - Drugs, including thalidomide, quinine
 - Cretinism
- First and second branchial arch syndromes include a variety of abnormalities with nonotologic and otologic manifestations
- Otologic abnormalities include:
 - Malformed or absent external ears
 - Atretic external auditory canal and impaired hearing
- Nonotologic features include:
 - Asymmetric facies
 - Temporomandibular joint
 - Neuromuscular abnormalities
 - Associated abnormalities of the cardiovascular, renal, and central nervous systems; Goldenhar syndrome, also known as oculoauriculovertebral dysplasia, is a first and second branchial arch syndrome characterized by ear tags and preauricular pits and fissures, epidermoids and lipodermoids, and vertebral column abnormalities.
- Of the approximately 2000 to 3000 profoundly deaf infants born yearly in the United States, 35% to 50% have a defined genetic origin for their hearing impairment.
- In approximately one third the hearing loss is syndromal or associated with other anomalies.
- In adults, approximately 20% of sensorineural hearing loss has a genetic cause.
- Etiologic factors vary with age.
- More than 50% of early-onset hearing loss is due to genetic factors, of which:
 - 60% to 70% are autosomal recessive (both parents carry the affected gene, involvement of the offspring is 25%)
 - 20% to 30% autosomal dominant (one parent carries the affected gene and the incidence of involvement of the offspring is approximately 50%)
 - 2% are X-linked
- In patients with late-onset hearing loss:
 - Approximately 20% are due to infections
 - About 7% due to trauma
 - 35% due to old age, heredity, and noise trauma
 - Approximately 35% of unknown cause

Hereditary sensorineural hearing loss includes the following categories:

- Autosomal-recessive hereditary sensorineural hearing loss:
 - Hereditary recessive sensorineural hearing loss without associated defects (about 50% of recessive hereditary deafness), including recessive congenital severe deafness, high-frequency deafness, mid-frequency deafness)
- Inborn errors of metabolism and deafness:
 - Albinism and deafness
 - Hurler syndrome (abnormality of mucopolysaccharide metabolism)
 - Tay-Sachs disease (ganglioside lipidoses and deafness)
 - Wilson disease (hepatolenticular degeneration and deafness)
- Degenerative diseases of the nervous system and deafness:
 - Friedrich ataxia (spinocerebellar ataxia, deafness)
- Congenital heart disease and deafness:
 - Jervell and Lange-Nielsen syndrome (cardiac conduction anomaly, deafness)
- Endocrine system disorders and deafness:
 - Pendred syndrome (nonendemic goiter and deafness)
- Ocular diseases and deafness
 - Usher syndrome (retinitis pigmentosa, deafness)
 - Cockayne syndrome (retinitis pigmentosa, mental retardation, dwarfism, retinal atrophy, deafness)
 - Alström syndrome (retinitis pigmentosa, obesity, diabetes mellitus, deafness)

Autosomal-dominant hereditary sensorineural hearing loss:

- Inborn errors of metabolism and deafness:
 - Tietze syndrome (albinism, deafness, abnormality of tyrosine metabolism)
 - Waardenburg syndrome (partial albinism, deafness, abnormality of tyrosine metabolism)
 - Schäfer syndrome (hereditary mental retardation, deafness, abnormality of tyrosine metabolism)
 - Hereditary mental retardation, homocystinemia, deafness, abnormality of methionine metabolism
- Nephropathies and deafness:
 - Alport syndrome (hereditary nephritis, deafness)
 - Muckle-Wells syndrome (hereditary nephritis, urticaria, amyloidosis, deafness)
 - Herrmann syndrome (hereditary nephritis, mental retardation, epilepsy, diabetes, and dominant nerve deafness)
- Ectodermal defects and deafness:
 - von Recklinghausen disease (vestibular schwannomas [unilateral, bilateral] and deafness)

- Dysplasia of the inner ear may be inherited, sporadic, or the result of chromosomal aberrations:
 - Typically, both ears are involved but perhaps not to a similar extent.
 - The classification of dysplasias of the osseous and membranous cochlea and vestibular labyrinth are divided into eight types:
 - Type I: isolated aplasia or dysplasia of the lateral semicircular canal
 - Type II: type I plus cochlear dysplasia
 - Type III: type I plus aplasia or rare club-shaped distension of the vestibule with rudimentary superior or posterior semicircular canals; a normal cochlea is present
 - Type IV: aplasia or dysplasia of all three semicircular canals plus severe cochlea dysplasia
 - Type V: aplasia or dysplasia of all three semicircular canals plus normal cochlea
 - Type VI: aplasia of all three semicircular canals plus cochlea aplasia
 - Type VII: normally configured vestibular labyrinth with aplasia of the cochlea
 - Type VIII: aplasia of the vestibular labyrinth and cochlea
- Above subclassifications of dysplasias of the osseous and membranous cochlea and vestibular labyrinth are based on earlier reports detailing the morphologic changes involving the cochlear modiolus, osseous spiral lamina, and contents of the vestibule and endolymphatic sac and duct. The original designations for the dysplasias of the cochlea and vestibular labyrinth in patients with profound congenital hearing loss include Michel type, Mondini type or Mondini-Alexander type, Scheibe type, and Siebenmann-Bing type:
 - Michel type includes bilateral aplasia of the cochlear and vestibular capsule with bilateral aplasia of the eighth cranial nerve.
 - Mondini type includes anomalies of the cochlea; this may include the presence of a single coil and/or flattening and underdevelopment
 - Scheibe type, referred to as cochleosaccular dysplasia, includes morphologic changes limited to the membranous cochlea and saccule. The utricle and semicircular canals are not involved.
 - Siebenmann-Bing type includes dysplasia of the membranous cochlea and vestibular labyrinth with a well-formed bony labyrinth (cochlear capsule).

Heterotopias (Choristomas) of the Middle Ear and Mastoid

Definition: Heterotopias include the presence of normal-appearing tissue(s) in an anatomic location in which they normally are not found.

Synonyms: Choristomas; ectopias

- Heterotopias that occur in the middle ear include salivary gland tissue and neuroglial tissue:
 - Presence of glial tissue in the middle ear may represent acquired encephalocele rather than heteropia; see next section.

Middle Ear Salivary Gland Heterotopia (Fig. 23-3)

- May present with unilateral conductive hearing loss, tend to occur more often in women and occurs over a wide age range

Fig. 23-3. Middle ear heterotopia.

- A,** Heterotopic salivary gland tissue within the middle ear composed of seromucous glands. Note the presence of middle ear attenuated cuboidal-appearing epithelium overlying the heterotopic salivary gland tissue at the top of the image.
- B,** Heterotopic sebaceous glands in the middle ear.

- Often arise in conjunction with facial nerve and ossicular chain anomalies:
 - The combination of facial nerve and ossicular chain anomalies may be explained on the basis of a second branchial arch developmental abnormality.
- Salivary choristomas of the middle ear may be associated with branchial arch abnormalities, most commonly the second arch, as well as abnormalities of the facial nerve, including:
 - Bilateral preauricular pits, conchal bands, an ipsilateral facial palsy, and bilateral Mondini-type deformities

Pathology

Gross

- Choristomas appear as a lobulated, nonpulsatile soft tissue mass lying in the middle ear space with an intact tympanic membrane.

Histology

- Salivary gland tissues include an admixture of seromucous glands and adipose tissue.

Treatment and Prognosis

- Conservative surgical removal is the preferred treatment.
- Choristomas often adhere to dehiscent facial nerve; if complete surgical resection will compromise the integrity of the facial nerve, then incomplete resection is justified.
- Biopsy for diagnostic purposes followed by observation is an alternative to surgical excision.

- Rarely, salivary gland ectopia may produce a salivary gland neoplastic proliferation (e.g., pleomorphic adenoma).

Middle Ear Neuroglial Heterotopia

- True neuronal heterotopias in which isolated neuroglial tissue is located in the middle ear and temporal bone without continuity with the central nervous system is rare.
- More common occurrence in which glial-type tissue is present within the middle ear/temporal bone is seen in association with an acquired encephalocele.

Acquired Encephalocele (Fig. 23-4)

- Represent herniation of the brain into the middle ear and mastoid via compromise of the tegmen, a thin bony shell that separates the middle ear and mastoid cavity from the temporal lobe:
 - Tegmen may be compromised or destroyed secondary to trauma or prior surgery, by a complication of otitis media, or due to a congenital defect.
 - Fracture of the temporal bone may also result in herniation of the brain into the middle ear and mastoid.
 - Some cases appear to have occurred spontaneously without known association with an underlying cause and/or without a history of trauma, tumor, cholesteatoma, or surgery of the mastoid or cranium.
- No gender predilection; may occur over a wide age range but tends to occur in older individuals
- Often represent an incidental finding in patients requiring surgery for chronic otitis media

Fig. 23-4. Acquired encephalocele.

A, Acquired encephalocele, in which normal CNS tissue characterized by the presence of neuroglial tissue herniates into the middle ear space. This patient had a long-standing history of chronic otitis media and had undergone multiple operations. **B**, In some examples of acquired encephalocele, there may be changes of reactive gliosis characterized by astrocytic hypertrophy and hyperplasia.

- Associated symptoms may include unilateral conductive hearing loss, persistent otorrhea, leakage of CNS tissue, and/or recurrent episodes of meningitis.
- In patients suspected of having ectopic neuroglial tissue in this site, radiologic imaging (e.g., CT scans) may prove valuable in identifying a defect and/or connection to the CNS.

Pathology

Histology

- Includes a heterogeneous population of cells, including glial cells, histiocytes, and mature lymphocytes; reactive alterations of the neuroglial tissue (gliosis) may be present
- In addition, granulation tissue and keratinizing squamous epithelium (cholesteatoma) may be present
- Immunohistochemistry:
 - Confirmation of neuroglial tissues includes reactivity with glial fibrillary acidic protein (GFAP).

Differential Diagnosis

- Chronic otitis media:
 - Fibrillary appearing stroma that are often present may simulate the appearance of neurofibrillary matrix
 - GFAP will assist in confirming or excluding the presence of neuroglial tissues.
- Glial neoplasms

Treatment and Prognosis

- Management for acquired encephalocele is surgical:
 - For defects smaller than 1 cm in diameter, the transmastoid approach can be used.
 - For defects larger than 1 cm, the combined transmastoid-minicraniotomy approach provides good access.
- Potential complications include brain abscess.

ACQUIRED LESIONS OF THE EAR

EXTERNAL EAR

Keloid (Figs. 23-5 and 23-6)

Definition: Nonneoplastic dermal fibroproliferative process representing exaggerated tissue response to trauma representing one extreme of the spectrum of reparative reactions of the skin.

- “Keloid” derived from the Greek word *chele*, meaning “claw-like,” describing the tendency for these lesions to extend beyond the site of injury

Clinical

- Equal gender predilection; can occur at any age but is most common in young adults under 30 years of age

Fig. 23-5. Keloids.

A, Keloid appearing as polypoid mass covered by thin, glistening, hairless skin. **B**, Keloid with associated ulceration.

Fig. 23-6. Keloid.

A, Keloid composed of haphazard fascicles of hyalinized collagen that blend with surrounding dermal fibers; the overlying cutaneous squamous epithelium is thin and devoid of dermal adnexa. **B,** Keloid treated by steroid injection resulting in small subepithelial steroid lakes.

- Common in dark-skinned people, especially in young black women who have had their ears pierced
- Most common sites include presternum, limbs, neck, and face; the latter include the earlobes and pinna.
- Most often are asymptomatic but may be associated with pruritus, paresthesia, and pain
- Often associated with a variety of cutaneous injuries, including surgery, ear piercing, BCG vaccinations, injections, burns, lacerations, insect bites; the development following injury may occur anywhere from weeks up to a year.

Pathology

Gross

- Often polypoid in appearance covered by thin, glistening, hairless skin; size is variable, usually measuring less than 2 cm; however, they may attain a diameter of several centimeters.

Histology

- Haphazardly arranged fascicles of hyalinized collagenous fibers with scattered fibroblasts and myofibroblasts
- Proliferation is not encapsulated but blends subtly with the surrounding dermal fibrous tissue:
 - Collagen bundles are often separated by dermal mucosubstance, creating an “edematous” appearance.
- Poorly vascularized with widely scattered dilated blood vessels
- Overlying epidermis is thin and atrophic, without dermal adnexal structures.
- Foreign body giant cell reaction is uncommon, except in patients treated with corticosteroid injection.
- Pools of amorphous mucin-like material may also be seen following steroid injection.

Differential Diagnosis

- Hypertrophic scar:
 - Lack the dense hyalinized collagenous fibers, have more delicate fibrillar collagen, and have a more orderly arrangement of the collagen and fibroblastic cells often with a parallel orientation to the skin surface
 - Mature hypertrophic scars generally do not have an abundance of mucosubstances and therefore have a more compact microscopic appearance.
 - Hypertrophic scars usually do not recur following excision.
- Dermatofibroma (DF) and dermatofibrosarcoma protuberans (DFSP):
 - Extremely low cellularity of keloids distinguishes it from DF and DFSP.

- In contrast to keloids there is hyperplasia of the overlying epidermis in DF and DFSP.
- Unusual variant of dermatofibroma characterized by keloidal-type changes and termed keloidal dermatofibroma has been described:
 - Clinically appear similar to usual DF
 - Characterized by keloidal-like collagen admixed with elements typically present in DF
- DFSP shows immunoreactivity for CD34.

Treatment and Prognosis

- Surgical excision is the preferred treatment.
- Recurrence rates of 40% following simple surgical resection have been reported.
- Intralesional steroid (triamcinolone) injections alone provide response rates of 50% to 100% with recurrence rates of 5% to 50% at 5 years:
 - Intralesional triamcinolone injections considered gold standard in nonsurgical management
 - Intralesional verapamil, independent of or in conjunction with triamcinolone, has shown efficacy in treatment of keloids (and hypertrophic scars) with flattening of the raised scars and regaining normal pigmentation.
- When surgery is followed by steroid injection or radiation therapy (10 Gy), recurrence rates are consistently below 50%.
- Intralesional injection of interferon or bleomycin has shown 50% reduction in size, and response appears to be limited to the area treated.
- Intralesional cryosurgery has emerged as a safe and effective new treatment by destroying the hypertrophic scar tissue with minimal damage to the skin surface.
- TGF- β (transforming growth factor beta) and PDGF (platelet-derived growth factor) play an integral role in the formation of keloids, and future development of selective inhibitors of TGF- β might produce new therapeutic tools with enhanced efficacy and specificity for treatment of keloids.

Idiopathic Cystic Chondromalacia of the Auricular Cartilage

(Figs. 23-7 and 23-8)

Definition: Benign cystic degeneration of the auricular cartilage of unknown cause.

Synonyms: Pseudocyst of the auricle; auricular or endochondral pseudocyst

Clinical

- Typically affects men and rarely seen in women; generally affects young and middle-aged adults
- Can occur along any portion of the auricle with the most common site adjacent to the helix

Fig. 23-7. Idiopathic cystic chondromalacia.

Idiopathic cystic chondromalacia appearing as a subepithelial swelling along the anterior pinna.

- Symptoms include unilateral, painless swelling of the auricular cartilage without overlying ulceration or erythema; symptoms develop over a period of weeks to years; may occur anywhere on the auricle but the scaphoid fossa (80%) is the most common site; occasionally lesions may be bilateral.
- Markedly elevated lactate dehydrogenase (LDH) levels may be found in aspirated fluid.
- Although trauma has been implicated in causing these lesions, there is no definitive connection to a prior traumatic event and the cause(s) for this condition remains unknown:
 - Belief that repeated trauma stimulated by such phenomena as sleeping on hard pillows, the wearing of motorcycle helmets, stereo headphones, or the Italian birthday custom of having one's auricle pulled
 - Ischemic necrosis of the cartilage or the abnormal release of lysosomal enzymes by chondrocytes may also be cofactors.
- May arise within a potential plane left during embryonic fusion of the auricular hillocks

Fig. 23-8. Idiopathic cystic chondromalacia.

A and B, At low magnification idiopathic cystic chondromalacia appears with subepithelial intracartilaginous thin walled cysts. In **B**, the cartilage appears black in this elastic stain. **C**, The cysts lack an epithelial lining and **(D)** are in part lined by granulation tissue.

Pathology

Gross

- Fluid-filled distended mass
- Excised tissue may include only a fragment of the cyst wall or, less often, a full-thickness excision of the ear.

- Intact cyst usually contains fluid described as “olive-oil-like.”
- Cyst wall consists of a 1- to 2-mm rim of cartilage.
- Cyst lining may be a smooth and glistening cartilaginous surface or may include roughened rust-colored patches.

- Cyst is usually an elongated cleft, but multifocal cystic degeneration may be seen.

Histology

- Changes are restricted to the cartilage within which irregular-shaped cystic areas are seen; cyst is the result of loss of cartilage.
- Cysts lack an epithelial cell lining (pseudocyst) and generally are devoid of content.
- Cystic cleft is often centrally placed in the cartilaginous plate.
- Rim of fibrous tissue may be seen along the inner portion of the cyst or a granulation tissue reaction composed of fibrovascular tissue, and scattered chronic inflammatory cells can be seen in association with the cysts.
- In long-standing cases fibrous tissue may essentially obliterate the cystic space.
- Some examples are characterized by a distinctly proliferative cartilaginous response, developing a thickened cartilaginous wall.
- Surrounding cartilage is unremarkable.

Differential Diagnosis

- Relapsing polychondritis
- Subperichondrial hematoma
- Chondrodermatitis nodularis chronicus helices

Treatment and Prognosis

- Complete surgical excision without distortion of the underlying cartilaginous plate is the preferred treatment and is curative.
- Due to the potential for surgical-related deformity, full-thickness resection is not advocated.
- In addition to the obvious cosmetic concerns, long-standing lesions may result in deformity of the ear.
- Steroid injection alone has been unsuccessful and may result in cartilage deformity.
- Incision and drainage or curettage have shown variable success; needle aspiration alone results in rapid reaccumulation of fluid but, when combined with bolster suture compression, long-term follow-up has shown an absence of recurrences.

Chondrodermatitis Nodularis Chronicus Helicis (CNCH)

(Figs. 23-9 and 23-10)

Definition: Idiopathic nonneoplastic ulcerative lesion of the auricle.

Synonyms: Winkler disease or nodule

Clinical

- More common in men in late middle age and older age groups; considered uncommon in women

Fig. 23-9. Chondrodermatitis nodularis chronicus helices.

Chondrodermatitis nodularis chronicus helices (CNCH) of the auricular anterior pinna (antitragal) appearing as a raised, oval nodule with central ulceration.

- Most frequently occurs along the superior portion of the helix; lateral helical, antihelical, and antitragal involvement also seen
- Spontaneously occurring unilateral painful nodule is the most common clinical presentation; manipulation of the lesion results in intense pain; pain is thought to result from the perichondrial involvement.
- Clinically, the lesions appear as round, reddish areas usually measuring less than 1 cm in diameter; many cases are clinically considered to be carcinomas.
- Cause remains unknown; however, several theories have been suggested, including:
 - Cold exposure
 - Actinic damage
 - Local trauma
 - Degenerative change with pressure necrosis
 - The skin of the auricle is thin with little subcutaneous fat and therefore may be unusually sensitive to injury; further, the vascular supply to the area is somewhat deficient with the avascular cartilage depending on the dermal circulation for its sustenance; these anatomic features may predispose the auricle to the development of CNCH.
- Winkler considered the underlying pathologic event to be a cartilaginous-based process; however, the cause appears to be linked to a primary cutaneous alteration because the cutaneous changes are more significant and a more constant feature.
- Likely that the development of CNCH is multifactorial and includes actinic damage

Fig. 23-10. CNCH.

A, Histologic features of CNCH include ulcerated epithelium with fibrinoid necrosis, associated granulation tissue, and an inflammatory cell infiltrate. **B,** The inflammatory cell infiltrate may extend into cartilage. **C,** Another example of CNHC in which inflammatory and granulation tissue process extend to subjacent cartilage with re-epithelialization of the surface ulceration.

Pathology

Gross

- Usually appears as a dome-shaped, discrete nodule with a scaly crust covering a central area of ulceration ranging in diameter from 3 to 18 mm, with an average of 7 mm:
 - Rarely, CNCH may achieve diameters of 2 to 3 cm.

Histology

- Central portion of the involved epidermis is ulcerated with adjacent epithelium showing acanthosis, hyper- and parakeratosis, and pseudoepitheliomatous hyperplasia.
- Base of the ulcer shows granulation tissue, edema, fibrinoid necrosis, and an acute and/or chronic inflammatory cell infiltrate.
- Granulation tissue and inflammatory process usually extend to and involve the perichondrium and cartilage.

Differential Diagnosis

- Basal cell carcinoma
- Squamous cell carcinoma
 - CNCH is frequently misdiagnosed as a cutaneous malignancy, particularly as basal cell carcinoma or squamous cell carcinoma.
 - Same mistake may be perpetuated by microscopic examination, particularly if the epidermal hyperplastic changes are misinterpreted as representing either squamous cell carcinoma or a hypertrophic actinic keratosis; careful attention to the extensive dermal changes and usually some degree of cartilaginous alterations, along with the well-demarcated nature of the epidermal proliferation and lack of cytologic atypia in the adjacent epidermis, should help in excluding a squamous neoplasm in cases of CNCH.

Treatment and Prognosis

- Complete surgical excision is the preferred treatment and is curative:
 - Surgery includes wedge excision or cartilage excision alone.
- In a minority of patient trials with injection of glucocorticoids directly into the lesion have been shown to be effective in eradicating the lesion.
- No malignant potential

Exostosis of the External Auditory Canal (Figs. 23-11 and 23-12)

Definition: Localized overgrowth of bone classically described as a reactive lesion consisting of a compact proliferation of layers of bone of varied size and

Fig. 23-11. Exostosis.

Excised external auditory canal (intact) exostosis appearing as a broad-based, mound-like bony proliferation.

appearance, including nodular, mound-like, pedunculated, or flat protuberances on the surface of a bone.

Synonym: Surfer's ear

NOTE: Broad-based lesions are referred to as exostosis; pedunculated lesions have been termed osteoma.

Clinical

- Broad-based outgrowths of bone arising from the wall of the external auditory canal
- Usually are multiple and bilateral
- Tend to remain asymptomatic until they reach a size sufficient to interfere with the normal egress of cerumen and exfoliated skin:
 - Obstruction of the external auditory canal may cause recurrent episodes of external otitis, conductive hearing loss, and tinnitus.
- Predilect to cold water swimmers and surfers, with the highest incidence being found in Australia and New Zealand:
 - White water kayakers are the first inland population to experience exostoses at the rates seen in coastal populations (e.g., surfers); earplugs may be protective.

Pathology

Gross

- Appearance of exostoses is usually better appreciated by the surgeon, as only fragments are available to the pathologist in most cases.
- The intact exostosis is a broad-based, mound-like bony proliferation that is similar in color and texture to normal cortical bone.

Fig. 23-12. Exostosis.

A, Exostosis composed of laminated compact bone creating an “onion skin–like” appearance on cross section lying beneath the intact but disrupted keratinizing squamous cells of the external auditory canal. **B**, Another external auditory canal benign osseous proliferation perhaps better designated as an osteoma composed of dense compact cancellous bone with intervening loose fibrovascular tissue lying beneath an intact keratinizing squamous epithelium.

Histology

- The bone is covered by a layer of periosteum with overlying thin skin.
- The periosteal layers are like the skin of an onion and usually lack trabecular architecture or marrow spaces.

Differential Diagnosis

- Osteoma:
 - Much less common lesion in relationship to the external auditory canal
 - Distinction between exostosis and osteoma is usually readily made on the basis of the clinical presentation; there has been some controversy regarding the ability to distinguish between the two lesions histologically; some authorities consider the lesions histologically different, whereas others do not find the microscopic features sufficiently distinctive to be separated.

Treatment and Prognosis

- Medical treatment resolves the symptomatic external otitis and related hearing loss.
- For patients who do not respond to medical treatment, transmeatal surgical excision is the preferred treatment.

Synovial Chondromatosis of the Temporomandibular Joint (TMJ)

(Figs. 23-13 and 23-14)

Definition: Reactive process of unknown pathogenesis characterized by the formation of multiple cartilaginous nodules in the synovium, with many becoming detached and floating within the joint space.

Synonyms: Synovial osteochondromatosis; synovial chondrometaplasia

Clinical

- Predilects to women and generally occurs in adults
- May present with preauricular swelling and limited motion of the joint with deviation of the mandible
- May involve the external auditory canal, resulting in an asymptomatic mass lesion
- Radiographic features include the presence of numerous radiopaque loose bodies within the region of the joint but destruction of bone is absent:
 - CT scan excellent to define bony surfaces of the articular joints but fails in detection of loose bodies when these are not yet calcified
 - MRI is gold standard when diagnosis is suspected because it can visualize loose bodies at early stage and also evaluate disk condition and eventual extra-articular tissue involvement

Fig. 23-13. Synovial chondromatosis with synovial bodies.

A, Sagittal image shows expansion of the joint capsule (*arrows*) with multiple low signal intensity rounded bodies in the joint. **B**, Coronal proton-density MR image showing expansion of the lateral and medial capsule walls (*arrows*), which indicates a neoplastic intraarticular process with multiple areas of low signal intensity consistent with synovial chondromatosis. **C**, Small bodies of cartilage material removed from this joint showing synovial chondromatosis. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 26-84, A-C, p 1589.)

- On T2-weighted imaging:
 - Signs of low signal nodules within amorphous iso-intensity signal tissues; signs of low and intermediate signal nodules within joint fluids used to detect loose cartilaginous nodules
- Intraoperatively, the lesion is usually confined to the joint space itself and is easily enucleated; on occasion the lesion may extend beyond the joint capsule into the parotid gland, auditory canal, temporal bone, or cranium.
- Rarely occurs in association with pseudogout (calcium pyrophosphate dihydrate deposition disease); see later.
- Pathogenesis:
 - Synovial chondromatosis is a condition in which foci of cartilage develop in the synovial membrane of a joint apparently through metaplasia of the sublining connective tissue of the synovial membrane.
 - Fibroblast growth factor 2 (FGF-2) found to be expressed in chondrocytes and fibroblast-like

Fig. 23-14. Synovial chondromatosis.

The histologic features of synovial chondromatosis of the temporomandibular joint include (A) subcutaneous well-delineated nodular proliferation of mature cartilage showing variable cellularity and (B) rather typical appearing chondrocytes (*right*) juxtaposed to chondrocytes with increased cellularity, including pleomorphic and hyperchromatic nuclei and occasional, binucleated chondrocytes (*left*).

cells of loose bodies and believed to be involved in the pathogenesis

- Clonal chromosomal alterations (chromosome 6 abnormalities) in synovial chondromatosis suggest this is a neoplastic lesion rather than a metaplastic/reactive process.
- Cell proliferation studies have shown intermediate proliferative activity of the cellular composition of synovial chondromatosis between enchondromas and chondrosarcomas.

Pathology

Gross

- Synovium may be diffusely studded with innumerable nodules.

- Nodules are polypoid or pedunculated with a delicate stalk, and vary in size from as small as 1 mm up to 3 cm.
- External surface varies from smooth to convoluted and granular.

Histology

- Consists of nodules of mature cartilage of varying cellularity within the synovium and lying loosely in the joint space.
- Cartilage may appear atypical with hypercellularity, hyperchromasia, binucleated chondrocytes, and increased mitoses.
- Calcification and ossification may be present.
- Immunohistochemistry:
 - No increase in proliferation activity as determined by Ki67 (MIB1) staining

Differential Diagnosis

- Chondrosarcoma:
 - Presence of increased cellularity with atypical features, including binucleated chondrocytes, may suggest a diagnosis of chondrosarcoma. In such examples, correlation with the radiographic appearance would be essential to differentiate these lesions. The radiographic features of synovial chondromatosis include the presence of numerous radiopaque loose bodies within the region of the joint.

Treatment and Prognosis

- Conservative surgical management is the preferred treatment.
- May rarely extend into the cranial cavity and skull base
- Reported cases of synovial chondrosarcoma suggest the possibility of malignant transformation of synovial chondromatosis.

MIDDLE AND TEMPORAL BONE

Cholesteatoma (Keratoma)

(Figs. 23-15 through 23-20)

Definition: Pseudoneoplastic lesion of the middle ear characterized by presence of stratified squamous epithelium that forms a saclike accumulation of keratin within the middle ear space with invasive growth; despite their invasive growth, cholesteatomas are not considered to be true neoplasms.

Synonyms: The term cholesteatoma is a misnomer in that it is not a neoplasm nor does it contain cholesterol; the designation of keratoma would be more accurate but the term cholesteatoma is entrenched in the literature.

Fig. 23-15. Cholesteatoma.

Otoscopic view of the pars flaccida retraction pocket (arrow) in the right tympanic membrane. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 18-40, p 1204.)

Fig. 23-16. Cholesteatoma.

Intraoperative appearance of cholesteatoma appearing as white mass/debris within the middle ear.

- Other designations include epidermal cyst or epidermal inclusion cyst of the middle ear.
- Cholesterol granuloma is not synonymous with cholesteatoma and these lesions are distinctly different pathologic entities and should not be confused with one another.
- Cholesteatomas may be divided into acquired and congenital types.

Fig. 23-17. Pars flaccida cholesteatoma.

A, Axial CT demonstrates a soft tissue mass with remodeling of the lateral attic wall (arrow). The ossicles are slightly medially displaced. **B**, Coronal CT image again demonstrates a soft tissue mass interposed between the lateral attic wall and malleus head. Note the blunted scutum (arrow). (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 18-41, p 1204.)

Acquired Cholesteatoma

Clinical

- More common in men than in women and are most common in the third to fourth decades of life
- Middle ear space is the most common site of occurrence:

Fig. 23-18. Cholesteatoma.

The histologic features of a cholesteatoma include the presence of stratified keratinizing squamous epithelium and subepithelial fibroconnective tissue; this histologic picture of a specimen from the middle ear is diagnostic for cholesteatoma.

Fig. 23-19. Cholesteatoma.

Cholesteatomatous involvement of a middle ear ossicle in which a fragment of keratinizing squamous epithelium (*left*) is seen involving bone.

Fig. 23-20. Cholesteatoma.

Left, Diagnostic findings of a cholesteatoma characterized by the presence of keratinizing squamous epithelium, which was identified from within the middle ear space. *Right*, The presence of keratin debris only is not considered diagnostic for a cholesteatoma irrespective of a high index of clinical suspicion for a cholesteatoma and/or a prior diagnosis of cholesteatoma. In the absence of the epithelial component, a diagnosis of cholesteatoma should not be rendered.

- Most acquired cholesteatomas arise in the pars flaccida portion of the tympanic membrane and extend into Prussak space:
 - Prussak space is bordered laterally by the pars flaccida (Shrapnell membrane), medially by the neck of the malleus, superiorly by the attachment of the pars flaccida to the tympanic ring near the scutum, and inferiorly by the lateral or short process of the malleus.
- Initially, cholesteatomas may remain clinically silent until extensive invasion of the middle ear space and mastoid occurs.
- Symptoms include:
 - Hearing loss, malodorous discharge, and pain and may be associated with a polyp arising in the attic of the middle ear or perforation of the tympanic membrane
 - External ear canal cholesteatomas generally occur in older aged individuals, present with otorrhea and unilateral chronic pain, and do not produce a conductive hearing loss.
- Otoscopic examination may reveal the presence of white debris within the middle ear, which is considered diagnostic.
- Radiology:
 - Given the localization to Prussak space, most acquired cholesteatomas displace the malleus medially and erode the adjacent bony scutum; from there the mass may extend posteriorly via

the epitympanum in the superior incudal space to the posterolateral attic and then via the aditus ad antrum to the antrum and mastoid air spaces.

- Radiographic evidence of widening of the aditus is an important diagnostic finding.
- Acquired cholesteatomas may occur in the external auditory canal:
 - Generally occur in older aged individuals
 - Present with otorrhea and unilateral chronic pain, does not produce a conductive hearing loss
- Pathogenesis:
 - Majority of cholesteatomas are acquired and either arise de novo without a prior history of middle ear disease or arise following a middle ear infection
 - A small percentage of cases are congenital (see below).
 - Pathogenesis of acquired cholesteatoma is thought to occur via migration of squamous epithelium from the external auditory canal or from the external surface of the tympanic membrane into the middle ear
 - Mechanism by which the epithelium may enter the middle ear probably is by a combination of events, including perforation of the tympanic membrane (particularly in its superior aspect referred to as the pars flaccida or Shrapnell membrane following an infection) coupled with invagination or retraction of the tympanic membrane into the middle ear as a result of long-standing negative pressure on the membrane secondary to blockage or obstruction of the eustachian tube.
 - Other theories by which cholesteatomas are thought to occur include traumatic implantation, squamous metaplasia of the middle ear epithelium, and congenital derivation.

Congenital Cholesteatoma

Definition: Cholesteatoma of the middle ear that exists in the presence of an intact tympanic membrane, presumably occurring in the absence of chronic otitis media that may result in perforation or retraction of the tympanic membrane.

Clinical

- No gender predilection; found in infants and young children
- Majority of cases of congenital cholesteatomas are found in the anterosuperior part of the middle ear
- In early lesions no symptoms and lesions are discovered by otoscopic examination; in later lesions the signs and symptoms may be the same as acquired cholesteatoma.

- Pathogenesis:
 - Small colonies of epidermoid cells referred to as epidermoid formations are found on the lateral anterior superior surface of the middle ear in temporal bones after 15 weeks' gestation.
 - During the first postpartum year the epidermoid colonies disappear; however, if the epidermoid cells do not disappear but continue to grow, they will become congenital cholesteatomas.

Pathology

- Similar pathologic findings for acquired and congenital cholesteatomas

Gross

- Cholesteatomas appear as a cystic white to pearly-appearing mass of varying size containing creamy or waxy granular material.

Histology

- Histologic diagnosis is made in the presence of a stratified keratinizing squamous epithelium, sub-epithelial fibroconnective or granulation tissue, and keratin debris.
- Essential diagnostic feature is the keratinizing squamous epithelium; presence of keratin debris alone is not diagnostic of a cholesteatoma.
- Keratinizing squamous epithelium is cytologically bland and shows cellular maturation without evidence of dysplasia.
- In spite of its benign histology, cholesteatomas are “invasive” and have widespread destructive capabilities:
 - Destructive properties result from a combination of interrelated reasons, including mass effect with pressure erosion of surrounding structures from the cholesteatoma and production of collagenase, which has osteodestructive capabilities by its resorption of bony structures and bone resorption.
 - Collagenase is produced by the squamous epithelial and fibrous tissue components of the cholesteatoma.
- Keratosis obturans (see below) is composed of loosely packed, irregularly arranged keratin squames in the external auditory canal.
- Immunohistochemistry:
 - Cytokeratins and p63 positive
- Ploidy analysis performed to determine whether cholesteatomas were low-grade squamous carcinomas found cholesteatomas to be diploid; due to a lack of overt genetic instability, cholesteatomas could not be considered to be malignant neoplasms.
- Cytogenetics and molecular genetics:

- Identification of upregulation of human microRNA-21(hsa-miR-21) concurrent with downregulation of potent tumor suppressor proteins PTEN and programmed cell death 4:
 - These proteins control aspects of apoptosis, proliferation, invasion, and migration.
 - Model for cholesteatoma proliferation through microRNA dysregulation
- Genes found to be induced or upregulated in cholesteatoma include:
 - Genes involved in cell proliferation and differentiation (e.g., calgranulin A, calgranulin B, psoriasin, thymosin beta-10)
 - Genes involved in cell invasion (e.g., cathepsin C, cathepsin D, cathepsin H)
- Upregulation of proliferating cell nuclear antigen (PCNA) and osteoclast stimulating factor-1 (OSF-1):
 - Two candidate proteins in the pathogenesis of cholesteatoma relating to cellular proliferation and bone destruction
- EGFR/PI3K/Akt/cyclinD1 signaling pathway is active in cholesteatoma and may play a role in cholesteatoma epithelial hyperproliferation.
- Keratinocyte growth factor (KGF), a mesenchymal cell-derived paracrine growth factor that specifically stimulates epithelial cell proliferation, is present in cholesteatomas:
 - Keratinocyte growth factor protein (KGFR) and mRNA localized in the epithelium in 72% of cases
 - Significant correlation between KGF+/KGFR+ expression and recurrence
 - KGF and KGFR may play a role in enhanced epithelial cell proliferative activity and recurrence of cholesteatomas.
- Angiogenesis and angiogenic growth factors are present in cholesteatoma:
 - Close relationship is seen between the density of capillaries, degree of inflammation, and expression of the angiogenic factors.
 - Increased number of microvessels
 - Angiogenesis enables and supports the sustained migration of keratinocytes into the middle ear cavity.
 - Represent a pivotal factor in the destructive behavior of middle ear cholesteatoma

Differential Diagnosis

- Squamous cell carcinoma:
 - In contrast to cholesteatomas, squamous cell carcinoma shows dysplastic or overtly malignant cytologic features with a prominent desmoplastic stromal response to its infiltrative growth
 - Cholesteatomas do not transform into squamous cell carcinomas.
- Epidermoid of the petrous apex (Fig. 23-21):
 - Represents an epidermoid cyst of this location and bears no relation to cholesteatoma of the middle ear
 - It is likely of congenital origin possibly arising from sequestration of epidermal cells at the time of closure of the medullary groove between the third and fifth embryonic week.
 - Usually affects people 20 to 35 years old
 - Symptoms may include ipsilateral headaches, involvement of the third division of the fifth cranial nerve, signs of extrinsic compression of the eustachian tube with middle ear effusion and conductive hearing loss, and signs of compression of the internal carotid artery with ischemic effects (e.g., blurring of vision and faintness); as the lesion enlarges there may be involvement of the seventh and eighth cranial nerves in the cerebellopontine angle with progressive facial paresis preceded by progressive facial spasms (seventh cranial nerve involvement) and progressive sensorineural hearing loss, vertigo (eighth nerve involvement)
 - The tympanic membrane frequently remains intact.
 - Diagnosis established on the basis of prolonged clinical course, seventh and eighth cranial nerve involvement, and imaging findings
- Keratosis obturans (KO):
 - Results when the normal self-cleaning mechanism of keratin maturation and lateral extrusion from the external auditory canal is defective, causing accumulation of keratin debris deep within the bony aspect of the external auditory canal.
 - Cause of KO remains unclear.
 - KO occurs most commonly in the first two decades of life, and symptoms generally relate to conductive hearing loss due to the keratin plug.
 - Pain is not an uncommon finding.
 - Keratin debris may exert pressure effects on the bony canal wall, resulting in widening of the external auditory canal, bone remodeling, and inflamed epithelium.
 - Histologic appearance is that of tightly packed keratin squames in a lamellar pattern.
 - Treatment for KO is debridement of the keratin plug.
 - In contrast to KO, external ear canal cholesteatomas generally occur in older aged individuals, present with otorrhea and unilateral chronic pain, do not produce a conductive hearing loss, and are composed histologically of loosely packed, irregularly arranged keratin squames that may erode or invade bone (Fig. 23-22).

Fig. 23-21. Petrous apex epidermoid.

A and **B**, Axial CT images in bone algorithm. There is extensive erosion of the petrous apex, including much of the otic capsule (**A**). Compare with the normal left side at the same level (**B**). **C**, Axial CT image in soft tissue algorithm. The epidermoid is hypodense. **D** to **F**, Axial T2-weighted image and pre- and post-contrast-enhanced T1-weighted images. The mass is hyperintense on T2-weighted sequence, hypointense on T1-weighted sequence, and does not enhance. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 20-173, p 1367.)

Fig. 23-22. External auditory canal cholesteatoma (EACC).

A, Coronal CT image shows soft tissue opacification of the EAC with erosions along the floor and roof (arrows). Soft tissue bulges into the middle ear cavity. At surgery, this was found to be an EACC with an intact but retracted tympanic membrane. **B**, Different patient. Coronal CT image demonstrates "punched-out" erosions (arrows) in the floor of the EAC with minimal associated soft tissue. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 18-8, p 1187.)

Treatment and Prognosis

- Complete surgical excision of all histologic components of the cholesteatoma is the preferred treatment.
- If not completely excised, cholesteatomas can have progressive and destructive growth, including widespread bone destruction, which may lead to hearing loss, facial nerve paralysis, labyrinthitis, meningitis, and epidural and/or brain abscess.

Langerhans Cell Histiocytosis (LCH) (Figs. 23-23 through 23-27)

Definition: Clonal proliferation of Langerhans cells, a cellular component of the dendritic cell system, occurring as an isolated lesion or part of a systemic (multifocal) proliferation.

Synonyms: Langerhans cell (eosinophilic) granulomatosis (LCG), eosinophilic granuloma

NOTE: The designation of Langerhans cell histiocytosis has been used to replace the previous nomenclature of the group of diseases termed histiocytosis X that included eosinophilic granuloma, Letterer-Siwe disease, and Hand-Schüller-Christian disease.

Clinical

- Tends to occur in males; most commonly occurs in the second to third decades of life

Fig. 23-23. Langerhans cell histiocytosis.

Young girl with temporal bone involvement by Langerhans cell histiocytosis presenting with swelling and ulceration of skin.

- Lesions are most often osseous based:
 - Most frequent osseous sites involved occur in the skull (including the middle ear and temporal bone)
- In patients with middle ear and temporal bone involvement, symptoms include aural discharge, swelling of the temporal bone area, otitis media, bone pain, otalgia, loss of hearing, and vertigo.

Fig. 23-24. Langerhans cell histiocytosis of the temporal bone.

The patient is a 2-year-old boy with a history of periauricular swelling and chronic otorrhea. **A** and **B**, Axial, pre- and post-contrast-enhanced, T1-weighted images. There is a large, avidly enhancing, soft tissue mass involving the left mastoid temporal bone and middle ear cavity, with invasion of the sigmoid sinus. **C**, T2-weighted image. The mass is heterogeneously hypointense, indicating hypercellularity. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 20-182, p 1374.)

- A single or multiple sharply circumscribed osteolytic lesion can be seen by radiographic studies.

Pathology

Histology

- Characterized by a proliferation of Langerhans cells (LC), which are arranged in sheets, nests, or clusters and composed of cells with reniform nuclei characterized by nuclear membrane lobations or indentations
- Nuclei have a vesicular chromatin with inconspicuous to small centrally located basophilic nucleoli and a moderate amount of eosinophilic cytoplasm.
- LCs may show mild pleomorphism and mitotic figures are uncommonly seen.
- An inflammatory cell infiltrate primarily consists of eosinophils and accompanies the LC proliferation; other inflammatory cells are present, including polymorphonuclear leukocytes, plasma cells, and lymphocytes.
- Foamy histiocytes and multinucleated giant cells may also be present:
 - These histiocytes may show phagocytosis of mononuclear cells.
- Immunohistochemistry:
 - LCs are diffusely immunoreactive with S100 protein and CD1a.

Fig. 23-25. Langerhan cell histiocytosis.

Langerhans cell histiocytosis characterized by the presence of sheet-like proliferation of Langerhans cells, which are the cells with round, vesicular nuclei showing lobation or indentation of the nuclear membrane and a moderate amount of eosinophilic cytoplasm; admixed inflammatory cells including eosinophils and mature lymphocytes are present.

Fig. 23-26. Langerhan cell histiocytosis.

Langerhans cell histiocytosis composed almost exclusively of characteristic Langerhans cells with characteristic lobation or indentation of the nuclear membrane; in this example there is almost complete absence of an associated inflammatory cell infiltrate.

Fig. 23-27. Langerhan cell histiocytosis.

The diagnosis of Langerhans cell histiocytosis is confirmed by immunoreactivity of Langerhans cells for (A) S100 protein (nuclear and cytoplasmic reactivity); (B) CD1a (membranous reactivity); (C) Langerin (cytoplasmic and membranous reactivity).

- Langerin, a type II transmembrane C-type lectin associated with the formation of Birbeck granules in LC, represents a highly selective marker for LCs and the lesional cells of LCH.
- Langerin immunoreactivity shows a membranous and granular cytoplasmic pattern.
 - Assists in substantiating the diagnosis of LCH and in differentiating LCH from other non-Langerhans cell histiocytic proliferations
- Foamy histiocytes and multinucleated giant cells are S100 protein and CD1a negative but react with CD68 (KP1).
- Electron microscopy:
 - Elongated granules referred to as Langerhans or Birbeck granules can be seen within the cytoplasm of the LCs.
- Cytogenetics and molecular genetics:
 - Detection of BRAF (V600E) mutation found in LCH:
 - May provide new opportunities for devising targeted therapy
- Like LC, the cells of Rosai-Dorfman disease are S100 protein reactive but differ in that these cells are nonreactive with CD1a and/or Langerin.
- Non-Hodgkin malignant lymphoma:
 - Differentiating LCH from a malignant lymphoproliferative disease is usually not problematic by light microscopy; if necessary, immunohistochemical stains help differentiate LCH from a malignant lymphoma

Treatment and Prognosis

- Different therapeutic approaches can be considered depending on the affected organ, including surgery, radiotherapy, and chemotherapy:
 - Surgical excision (curettage) and low-dose radiotherapy for isolated temporal bone disease
 - Chemotherapy used for multifocal and systemic disease
- Prognosis for isolated disease considered very good
- Recurrence may be part of a systemic or multifocal process and generally occurs within 6 months of the diagnosis.
- Failure of a new bone lesion to occur within 1 year of diagnosis is considered a cure.
- In general, the younger the patient at onset of disease and the more extensive the involvement (multiple sites including bone and viscera), the worse the prognosis.

Differential Diagnosis

- Extranodal sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease):
 - May occasionally involve the ear and temporal bone region

INFECTIOUS AND INFLAMMATORY LESIONS

NECROTIZING EXTERNAL OTITIS (NEO)

(Figs. 23-28 through 23-30)

Definition: Virulent and potentially fatal form of external otitis related to *Pseudomonas aeruginosa* infection.

Synonyms: “Malignant” external otitis; necrotizing granulomatous otitis

Clinical

- No gender predilection; primarily affects older aged patients
- Typical clinical setting is that of a diabetic patient and/or a patient who is chronically debilitated or immunologically deficient although NEO may occur in nondebilitated patients.
- Originates in the external auditory canal with initial symptoms of an acute otitis externa and progression of disease pain, purulent otorrhea, and swelling.

Fig. 23-28. Necrotizing external otitis.

Necrotizing external otitis characterized by a swollen draining ear with a necrotic-appearing exudate.

Fig. 23-29. Malignant otitis externa with osteomyelitis of the skull base.

A, Axial CT image in bone window in this patient with diabetes and otitis externa demonstrates extensive destruction of the right basiocciput (*arrows*). The right mastoid air cells are opacified. **B** and **C**, Axial contrast-enhanced T1-weighted image and axial T2-weighted image demonstrate a large fluid collection in the right basiocciput extending to the pharyngeal region with irregular peripheral enhancement (*arrows*). Fluid opacification of the right mastoid air cells is again seen. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 18-5, p 1185.)

- With time, the infectious process may extend into the surrounding soft tissue structures (cellulitis), cartilage (chondritis), bone (osteomyelitis), base of skull, and middle ear space, leading to cranial nerve palsies, meningitis, intracranial venous thrombosis, and brain abscess.
- Pathogenesis:
 - Felt to be caused by tissue ischemia secondary to an underlying predisposing pathologic state (diabetic angiopathy) and a migratory defect of polymorphonuclear leukocytes related to systemic disease

Fig. 23-30. Necrotizing external otitis.

The histology of necrotizing external otitis with epithelial ulceration, an acute and chronic inflammatory cell infiltrate extending to bone and thick, acellular collagenous bands replacing most of the subcutis tissues.

- These host factors impede the inflammatory response to infection, and combined with the destructive devices of *P. aeruginosa* are thought to be responsible for lethal potential of NEO
- The microorganism, by virtue of its endo- and exotoxins, neurotoxins, collagenases, and elastases, is capable of causing rapid extensive tissue necrosis and necrotizing vasculitis that compounds the destruction.

Pathology

Gross

- Changes most pronounced in the osseous portion of the external canal, where the destructive infection usually begins; in this area, the skin becomes ulcerated, leaving a layer of thick granulation tissue covering the exposed and irregularly eroded bone, usually along the anterior and inferior surfaces of the external auditory canal
- Necrotic tissue is abundant in fully developed NEO, and may, along with purulent exudate, obstruct the canal.

Histology

- Histologic appearance dominated by the presence of necrotic material and exuberant granulation tissue
- Squamous epithelium is commonly ulcerated; intact epithelium may show marked reactive and/or atypical changes, including pseudoepitheliomatous hyperplasia adjacent to denuded areas.
- Diffuse heavy acute and chronic inflammation is seen in the subcutis, and a necrotizing vasculitis is commonly present.

- Thick, acellular collagen is seen replacing most of the tissue extending from the cartilage to the overlying dermis.
- Bone and cartilage are necrotic, with acute and chronic inflammatory cells massively infiltrating adjacent viable bone; sequestra of nonviable bone or cartilage may be seen.
- Dermis is eventually replaced by acellular collagen.
- Histochemistry:
 - Gram-negative bacilli are easily demonstrated by tissue Gram stain.

Differential Diagnosis

- Squamous cell carcinoma:
 - Infectious nature of NEO is usually evident from the clinical course and the histologic findings.
 - Presence of squamous epithelial pseudoepitheliomatous hyperplasia may suggest a squamous cell carcinoma.
 - Conversely, squamous cell carcinoma, if associated with extensive necrosis, may elude diagnosis by biopsy, yielding only necroinflammatory material such as one finds in NEO.
 - Occasionally the clinical presentation of squamous cell carcinoma of the external auditory canal may closely mimic NEO or the two diseases may occur concurrently.

Treatment and Prognosis

- Antibiotics, surgical debridement, and control of diabetes in patients suffering from that disease are the preferred treatments.
- Cures can be achieved with early recognition and aggressive treatment:
 - Combination therapy with intravenous ceftazidime and oral fluoroquinolone remains relevant despite concerns of culture-negative cases and multidrug-resistant *Pseudomonas*.
 - Fungal (aspergillus, others) and polymicrobial temporal bone infections have been reported with increasing frequency, and in culture-negative and/or multidrug-resistant cases, considerations should be given to causes by organisms other than *P. aeruginosa*.
- Hyperbaric oxygen therapy may be used as an adjunctive modality.
- Despite advances in antibiotic treatment, a significant proportion of patients succumb to this disease.
- Mortality rates may exceed 75% if the diagnosis and treatment are delayed.
- Death may result from extensive spread of the infection to adjacent structures, including intracranial involvement:
 - Involvement of the clivus portends a poorer prognosis.

OTITIS MEDIA

(Figs. 23-31 through 23-34)

Definition: Acute or chronic infectious disease of the middle ear space.

Clinical

- No gender predilection; may occur at any age but is predominantly a childhood disease particularly common in children under 3 years of age.
- Symptoms include fever, otalgia, and decreased hearing typically preceded by several days of an upper respiratory tract infection.
- Most common organisms implicated in causing disease are *Streptococcus pneumoniae* and *Haemophilus influenzae*.

Fig. 23-31. Chronic otitis media.

A, Chronic otitis media with associated glandular metaplasia. The metaplastic glands are unevenly distributed and proliferate in the setting of fibrosis and chronic inflammation; the metaplastic glands are of variable size and shape and contain thin (serous) fluid. **B**, Metaplastic glands are lined by a low cuboidal epithelium and contain serous-appearing fluid; along the superior aspect hair-like (cilia) structures are present.

- Otoscopic examination reveals a hyperemic, opaque, bulging tympanic membrane with limited mobility; purulent otorrhea may be present.
- Bilateral involvement is not uncommon.
- Middle ear infection is thought to result from infection via the eustachian tube at the time of or following a pharyngitis (bacterial or viral).

Pathology

Gross

- No specific macroscopic features; the tissue specimens usually are received as multiple small fragments of soft to rubbery granulation-appearing tissue.

Fig. 23-32. Chronic otitis media.

Tympanosclerotic foci appearing as mineralized debris are seen in association with other alterations of chronic otitis media, including glandular metaplasia and fibrosis.

Fig. 23-33. Cholesterol granuloma.

Cholesterol granuloma appearing as empty, irregular-shaped clefts or as spaces surrounded by a foreign body giant cell reaction; fresh hemorrhage and hemosiderin pigment deposition are present.

Fig. 23-34. Complications of chronic otitis media.

Clinical findings that can be seen as complications of chronic otitis media may include (A) acute mastoiditis and (B) chronic mastoiditis.

- If tympanosclerosis is present, then the tissues may be firm to hard, consisting of calcific debris.

Histology

- In general, all of the tissue fragments should be processed for histologic examination.
- Histology of otitis media varies and depends on the disease state.

Acute Otitis Media

- Virtually never a surgical disease
- Middle ear mucosa, also referred to as the mucoperiosteum, responds to infection with inflammation, hyperemia, polypoid thickening, and edema.
- Inflammatory infiltrate in acute otitis media is composed predominantly of polymorphonuclear leukocytes with a variable admixture of chronic inflammatory cells.
- Secretory otitis media refers to an otitis media with associated effusion behind an intact tympanic

membrane; the exudate may be serous, hemorrhagic, fibrinous, mucoid, purulent, or an admixture of types.

- Acute otitis media usually heals by resorption by the mucoperiosteum.
- Localized destruction of the middle ear ossicles may occur, and granulation tissue may develop resulting in scar formation; fibrosing osteitis is seen in areas of bone destruction that may result in reactive sclerotic bone.
- Acute otitis media may be superimposed on chronic otitis media.

Chronic Otitis Media

- Histologic changes include a variable amount of chronic inflammatory cells consisting of lymphocytes, histiocytes, plasma cells, and eosinophils; multinucleated giant cells and foamy histiocytes may be present.
- Middle ear cuboidal epithelium may or may not be seen.

- Glandular metaplasia, a response of the middle ear epithelium to the infectious process, may be present:
 - Glands tend to be more common in nonsuppurative otitis media than in suppurative otitis media.
 - Metaplastic glands are unevenly distributed in tissue.
 - Glands are variably shaped and are separated by abundant stromal tissue.
 - Glands are lined by a columnar to cuboidal epithelium with or without cilia or goblet cell metaplasia.
 - Glandular secretions may or may not be present so that the glands may appear empty or contain varying secretions, including thin (serous) or thick (mucoid) fluid content.
- In addition to the inflammatory cell infiltrate and glandular metaplasia, other histopathologic findings that usually are seen in association with COM or represent sequelae of chronic otitis media include:
 - Fibrosis, granulation tissue, tympanosclerosis, cholesterol granulomas, and reactive bone formation
- Due to the presence of scar tissue, the middle ear ossicles may be destroyed (partial or total) or may become immobilized.
- Perforation of the tympanic membrane pars tensa may occur with resulting ingrowth of squamous epithelium, potentially leading to the development of cholesteatoma.

Tympanosclerosis (Fig. 23-32)

- Represents dystrophic mineralization (calcification or ossification) of the tympanic membrane or middle ear that is associated with recurrent episodes of otitis media.
- Incidence of tympanosclerosis in otitis media varies from 3% to 33%.
- Tympanosclerosis of the tympanic membrane can be seen in children following myringotomy and tube insertion; in this setting the tympanosclerotic foci may or may not be permanent.
- Tympanosclerosis of the middle ear typically affects older patients, represents irreversible accumulation of mineralized material, and is associated with conductive hearing loss.
- On gross examination, tympanosclerotic foci may be localized or diffuse and appear as white nodules or plaques.
- Histologically, dense “clumps” of mineralized calcified or ossified material or debris can be seen within the stromal tissues or in the middle (connective tissue) aspect of the tympanic membrane.
- Tympanosclerosis may cause scarring and ossicular fixation.
- Tympanosclerosis may occur independent of otitis media.

Cholesterol Granuloma (Fig. 23-33)

- Represents a foreign body granulomatous response to cholesterol crystals derived from the rupture of red blood cells with breakdown of the lipid layer of the erythrocyte cell membrane.
- Arises in the middle ear in any condition in which hemorrhage occurs (e.g., otitis media) combined with interference in drainage and ventilation of the middle ear space; otoscopic picture is referred to as “blue ear syndrome.”
- Cholesterol granuloma of the middle ear may present as idiopathic hemotympanum; patients may also complain of hearing loss and tinnitus.
- Involvement of the petrous apex is more likely to be associated with sensorineural hearing loss; headaches, cranial nerve deficits, and rarely bone erosion with involvement of the posterior or middle cranial fossa may occur.
- Histology includes the presence of irregular-shaped, clear-appearing spaces surrounded by histiocytes and/or multinucleated giant cells (foreign body granuloma).
- Cholesterol granulomas are not related to cholesteatomas but may occur in association with or independent of a cholesteatoma.
- Cholesteatomas may or may not be associated with otitis media.

Differential Diagnosis

- Middle ear adenoma:
 - Pathologic alterations are generally straightforward, but secondary changes such as glandular metaplasia of the surface epithelium, the result of chronic infection, may occur that might be confused with a true gland-forming neoplasm (e.g., middle ear adenoma).
 - In middle ear adenomas the histology is dominated by the presence of a diffuse glandular and/or solid cell proliferation rather than the haphazard arrangement of the (metaplastic) glands as occurs in chronic otitis media.
 - Identification of cilia is confirmatory of middle ear glandular metaplasia and is a feature not found in association with middle ear adenomas.
- Cholesteatoma
- Langerhans cell histiocytosis
- Rhabdomyosarcoma:
 - In view of the fact that the inflammatory cell infiltrate seen in cases of otitis media may be extremely dense, the pathologist must be vigilant in evaluating these specimens, especially in the pediatric age group so as not to overlook the presence of rhabdomyoblasts and a diagnosis of rhabdomyosarcoma.

- Similarly, the inflammatory cell infiltrate may overrun and obscure Langerhans cells and a diagnosis of Langerhans cell histiocytosis.

Treatment and Prognosis

- Antibiotic therapy directed at the specific pathogen is curative
- Recurrent infections of the middle ear are common, especially in the pediatric population.
- In adults, an unresolving otitis media should warrant detailed examination of the nasopharynx to rule out the presence of a (malignant) neoplasm (i.e., nasopharyngeal carcinoma).
- Squamous cell carcinomas of the middle ear typically arise in patients suffering from (long-standing) chronic otitis media.
- In the antibiotic era, complications associated with otitis media are not generally seen; however, if left unchecked, complications of otitis media occur, which can be divided into:
 - Intratemporal complications
 - Intracranial complication

Intratemporal Complications of Otitis Media

- Include mastoiditis, petrositis, labyrinthitis, and facial nerve paralysis

Mastoiditis

- Due to the continuity of the middle ear space with the mastoid cavity, some degree of mastoiditis can be expected to occur in patients with otitis media; infrequently, acute suppurative mastoiditis occurs.
- Pneumococci and group A streptococci represent the more frequent pathogens in mastoiditis, whereas *Streptococcus pneumoniae* and *Haemophilus influenzae* representing the more common bacteria implicated in otitis media are uncommonly associated with mastoiditis.
- Mastoiditis is the most frequent complication of otitis media (acute and chronic).
- In contrast with the mild form of mastoiditis that frequently occurs in otitis media, the clinically severe form of mastoiditis results in bone destruction.
- Inflammatory destruction of bone may result in necrosis and abscess formation; bone resorption and repair lead to new bone formation typified by the presence of immature woven bone and sclerosis.

Petrositis

- Petrositis or petrous apicitis represents extension of the inflammation of the middle ear or mastoid cavity into the pneumatized cells of the petrous apex, which can occur by direct extension via the pneumatized

air cells of the petrous pyramid or via thrombophlebitis through the small vascular channels of the temporal bone.

- Osteitis and osteomyelitis of the petrous apex require pneumatization of the petrous pyramid, but the extent of pneumatization is not a factor in the development of petrositis.
- Petrositis occurs in two clinical forms:
 - Apical:
 - Characterized by its tendency to extend into the sphenoid bone and skull base, formation of abscesses in the nasopharynx and neck, and its potential source for otogenic septicemia
 - Paralabyrinthine:
 - Involves the paralabyrinthine cells around the semicircular canals and the internal auditory canal
 - Empyema of the of the endolymphatic sac with extension into the posterior cranial fossa and involvement of cranial nerves may occur.
 - Hematogenous dissemination via the petrosal and cavernous sinuses may occur.

Labyrinthitis

- Inflammation of the inner ear and includes pathologic changes of the labyrinth that arise in response to a variety of injuries, including infectious, inflammatory, and traumatic
- Can occur due to complications of otitis media or meningitis or from seeding of microorganisms via the vascular system
- Based on the pathologic changes seen, labyrinthitis can be classified into serous, suppurative, chronic, viral, and ossifying.
- Clinical manifestations of labyrinthitis depend on the severity and extent of the pathologic changes, varying from transient mild vertigo that might accompany an upper aerodigestive tract infection to severe vertigo with nystagmus and profound sensorineural hearing loss caused by suppurative labyrinthitis.
- Serous labyrinthitis is the mildest form of labyrinthitis, representing reactive changes in response to an irritant to the region as might occur secondary to either acute or chronic otitis media but without direct bacterial invasion of the inner ear:
 - In serous labyrinthitis there is accumulation of granular eosinophilic material within the labyrinth and/or perilymphatic spaces; mild endolymphatic hydrops may be seen
- Suppurative labyrinthitis is the result of bacterial invasion of the inner ear originating in the middle ear/temporal bone region (tympanogenic labyrinthitis) or from the meninges (meningogenic labyrinthitis):

- In suppurative labyrinthitis, an acute inflammatory infiltrate, including polymorphonuclear leukocytes, is present in the perilymphatic spaces and surrounding tissues with identifiable bacterial colonies.
- Gram stain may be of assistance in the identification of bacteria.
- With time there is necrosis and destruction of the sensory end organs and the membranous labyrinth.
- Chronic labyrinthitis may be focal or diffuse and results from a local osteitis of the otic capsule as a consequence of a previous acute suppurative labyrinthitis or as a result of a chronic inflammatory process of the membranous labyrinth:
 - This type of labyrinthitis may be associated with sudden or gradual loss of hearing and balance.
- Ossifying labyrinthitis is the end stage of suppurative labyrinthitis and is characterized by the new bone formation in the labyrinth likely representing an osseous metaplasia:
 - Histologic changes in ossifying labyrinthitis include ossification of the labyrinthian structures in the absence of an inflammatory infiltrate.
 - Designation of labyrinthitis for this process is liberally applied.
- Viral labyrinthitis is the result of generalized viral infection such as mumps, measles, and cytomegalovirus (CMV) infection with involvement of the scala media and vestibular end organs resulting in sensorineural hearing loss:
 - Viral labyrinthitis produce viral cytopathic changes in the scala media (stria vascularis, tectorial membrane, and organ of Corti) with associated cellular swelling, degeneration, cyst formation, and destruction.
- Complications of labyrinthitis include extension and involvement of intracranial structures, including meningitis, venous thrombophlebitis, intracranial abscess, facial nerve paralysis, and otitic hydrocephalus.

Intracranial (Endocranial) Complications

- Intracranial complications of otitis media include meningitis, lateral sinus thrombophlebitis, and brain abscess.

Miscellaneous Infections of the Ear and Temporal Bone

- Uncommonly, otitis media may be caused by:
 - Tuberculosis
 - Syphilis
 - Fungi, including *Candida*, *Mucor*, *Cryptococcus*, and *Aspergillus* and actinomycosis

- Viruses including herpes, cytomegalovirus (CMV), rubella, rubeola, and mumps can infect this region and may result in labyrinthitis and sensorineural hearing deafness.
- The setting for some of these infections, particularly mycoses, is in patients who are diabetic, debilitated, and/or immunosuppressed.
- In patients infected with human immunodeficiency virus (HIV) infection or who suffer from acquired immune deficiency syndrome (AIDS), *Pneumocystis jiroveci* (previously *carinii*) may seed from pulmonary lesions to the middle ear and temporal bone; in this setting (Fig. 23-35):
 - Initial clinical presentation may occur as an aural polyp.

Fig. 23-35. HIV-infected patient who presented with an aural polyp.

The polyp was removed and histologically showed (A) ulceration of the squamous epithelium with a submucosal acellular, eosinophilic “foamy” appearing infiltrate; (B) Gomori methenamine stain revealed numerous clusters of *Pneumocystis jiroveci* (previously *carinii*) microorganisms in which the cysts are black appearing as round, ovoid, or collapsed cuplike structures within the foamy exudate.

- Histologic examination shows characteristic foamy exudate containing the causative microorganisms:
 - Organisms best visualized by GMS stain in which cysts appear as round, ovoid, or collapsed cuplike structures measuring 3.5 to 7 microns in diameter with a membrane of variable thickness.

Differential Diagnosis

- Myospherulosis (see Section 1 on the Sinonasal Tract for illustrations):
 - Iatrogenically induced pseudomycotic lesion resulting from the interaction of red blood cells and petrolatum-based ointments
 - Myospherules originate from red blood cells, which react with petrolatum or lanolin found in ointment used.
 - Common sites of occurrence in the head and neck region include the nasal cavity and paranasal sinuses and occasionally the middle ear.
 - Typically, prior to the development of a mass patients give a recent history of prior surgery followed by packing of the area with a petrolatum-based ointment.
 - Histologically, myospherulosis is characterized by the presence of cysts devoid of an epithelial lining (pseudocysts) embedded within fibrotic tissue with an associated chronic inflammatory infiltrate composed of lymphocytes, histiocytes, giant cells, and plasma cells; the pseudocysts contain round, saclike structures called parent bodies; these parent bodies in turn contain numerous spherules or endobodies.
 - Special stains for fungi are invariably negative and assist in differentiating myospherulosis from fungal infections (e.g., rhinosporidiosis, coccidioidomycosis).
 - Treatment is symptomatic.

OTIC (AURAL) POLYP

(Figs. 23-36 and 23-37)

Definition: Inflammatory polypoid proliferation originating from the middle ear mucosa secondary to chronic otitis media.

Synonyms: Inflammatory aural polyp; aural polyp

Clinical

- No gender predilection; may occur at any age
- Symptoms include a otorrhea, conductive hearing loss, and/or a mass protruding from the external auditory canal.
- Despite origin from the middle ear, otic polyps may perforate the tympanic membrane with extension into the external auditory canal:

Fig. 23-36. Otic polyp.

Otic polyp appearing as a polypoid lesion that had perforated the tympanic membrane presenting as an external auditory canal mass.

Fig. 23-37. Otic polyp.

A, Otic polyp composed of a heterogeneous inflammatory cell infiltrate including neutrophils, mature plasma cells, lymphocytes, and multinucleated giant cells. **B,** Admixture of neutrophils and mature plasma cells, the latter containing large eosinophilic immunoglobulins referred to as Russell bodies or Mott cells.

- In this situation, the polyp may appear to be originating from the external auditory canal.
- Results secondary to chronic otitis media with perforation of the tympanic membrane and extension from the middle ear into the external auditory canal
- In large polyps completely obstructing the external ear, radiographic studies are an invaluable aid in identifying the origin of the polyp.
- In long-standing cases destruction (partial or complete) of the ossicles may occur.
- May rarely occur in association with Samter triad:
 - Tend to be bilateral, associated with conductive hearing loss, persistent otorrhea, and aural fullness
 - May represent a secondary immunologic dysfunction and chronic otologic inflammation from Samter syndrome

Pathology

Gross

- Polypoid, soft to rubbery, tan-white to pink-red appearing tissue

Histology

- Cellular polypoid mass primarily consisting of a chronic inflammatory cell infiltrate, including mature lymphocytes, plasma cells, histiocytes, and eosinophils.
- Relative to the plasma cells, Russell bodies or Mott cells containing large eosinophilic immunoglobules can be seen and are indicative of a benign plasma cell proliferation.
- Polymorphonuclear leukocytes may be present.
- Stroma includes granulation tissue varying in appearance from edematous and richly vascularized to fibrous with a decreased vascular component.
- Multinucleated giant cells may be present.
- Cholesterol granulomas and calcific debris (tympanosclerosis) may be present.
- When the epithelium is present it appears as pseudostratified columnar or cuboidal cells with or without cilia and may demonstrate squamous metaplasia; a (metaplastic) glandular proliferation may be present
- Histochemistry:
 - Special stains for microorganisms (fungi, spirochetes, mycobacteriae, protozoa, and parasites) are negative but are indicated to rule out an infectious cause.

Differential Diagnosis

- Langerhans cell histiocytosis:
 - Inflammatory cell infiltrate may overrun and obscure Langerhans cells and a diagnosis of Langerhans cell histiocytosis:

- Langerhans cells immunoreactive for S100 protein, CD1a, and Langerin
- Middle ear adenoma
- Rhabdomyosarcoma:
 - In view of the fact that the inflammatory cell infiltrate may be extremely dense, the pathologist must be vigilant in evaluating these specimens, especially in the pediatric age group so as not to overlook the presence of rhabdomyoblasts and a diagnosis of rhabdomyosarcoma.
 - If rhabdomyosarcoma is suspected, immunohistochemical for desmin, myogenin (myf-4), and myoglobin will assist in diagnosis and differential diagnosis.
- Hematolymphoid neoplasms
 - In general, the presence of a mixed cell population of chronic inflammatory cells is benign so that a diagnosis of a malignant lymphoproliferative process is not an issue.
 - Rarely, lymphomatous or leukemic involvement of the middle ear and temporal bone occur secondary to systemic disease.
 - The dense plasma cell component may lead to consideration of a plasmacytoma; although plasma cell dyscrasia may rarely occur in this site, the presence of mature plasma cells, Russell bodies, and polyclonality by immunohistochemistry should preclude a diagnosis of plasmacytoma.
- Other neoplasms that may present as aural polyps include:
 - Meningioma
 - Malignant melanoma
 - Metastatic renal cell carcinoma
 - Adenoid cystic carcinoma

Treatment and Prognosis

- In the absence of an infectious cause, local surgical excision is curative.

MALAKOPLAKIA (Fig. 23-38)

Definition: Malakoplakia is an inflammatory disease that usually involves the genitourinary tract and may rarely occur in the middle ear. Malakoplakia is derived from Greek and means “soft plaque.”

Clinical

- Extremely uncommon lesion in the head and neck; the middle ear is one of the reported sites of occurrence.
- No specific demographics
- Symptoms relate to chronic otitis media and conductive hearing loss.

Fig. 23-38. Malakoplakia.

Malakoplakia of the middle ear composed of solid sheets of histiocytes with granular to vacuolated cytoplasm (so-called Hanseman cells) and the presence of a single intracytoplasmic targetoid basophilic inclusion referred to as Michaelis-Gutman body (arrow).

Pathology

Histology

- Light microscopic features include the presence of solid sheets of histiocytes with slightly granular to vacuolated cytoplasm (so-called Hanseman cells) admixed with inflammatory cells, including lymphocytes, plasma cells and neutrophils.
- Intracytoplasmic diastase-resistant PAS-positive targetoid basophilic inclusion bodies termed Michaelis-Gutmann bodies can be seen within occasional cells:
 - These inclusions or calcospherites, which can also be seen extracellularly, contain calcium and frequently iron salts, thereby showing reactivity with von Kossa stain for calcium and Prussian blue stain for iron.
- Malakoplakia is believed to represent an unusual host response to infection with a variety of organisms and ultrastructurally phagolysosomes that have ingested breakdown products of bacteria such as *E. coli* have been found.

Treatment and Prognosis

- Curettage is curative.

AUTOIMMUNE, SYSTEMIC, AND DEGENERATIVE DISEASES OF THE EAR

RELAPSING POLYCHONDritis (RP) (Figs. 23-39 and 23-40)

Definition: Uncommon systemic episodic or relapsing disease characterized by progressive degeneration of cartilaginous structures throughout the body.

Synonym: Polychondropathia

Clinical

- Equal gender predilection; may occur at any age with symptoms most frequently occurring in the fifth through seventh decades of life
- May affect any cartilage tissue in the body
- Auricular cartilage is involved, usually bilaterally, in nearly 90% of patients.
- Affected ear is erythematous, swollen, and very tender.
- In advanced cases there may be distortion of the pinna due to destruction of the cartilage.
- Overlying skin is not ulcerated.
- Disease manifestations relapse with severity and frequency of occurrence and are markedly variable.
- Progression of disease may result in “cauliflower” ears and “saddle” nose deformities.
- Involvement of the audiovestibular system may result in hearing loss (conductive, sensorineural, or mixed).
- Other cartilaginous sites, as well as noncartilaginous sites, of the body may be involved, including:
 - Arthropathy (large and small joints)
 - Laryngotracheal and bronchial chondritis
 - Nasal chondritis
 - Cardiovascular complications (valvular insufficiency, aneurysm)
 - Ocular manifestations (episcleritis, conjunctivitis, retinopathy)
 - Cutaneous involvement (oral and genital ulcers)
- Arthritic involvement of costochondral, sternoclavicular, and sternomanubrial joints is common.
- Clinical diagnostic criteria for RP are defined by three or more of the following:
 - Recurrent chondritis of both auricles
 - Nonerosive inflammatory arthritis; chondritis of nasal cartilages
 - Ocular inflammation including conjunctivitis, keratitis, scleritis/episcleritis, and/or uveitis
 - Chondritis of the upper respiratory tract involving the larynx and/or tracheal cartilages
 - Cochlear and/or vestibular damage manifested by sensorineural hearing loss, tinnitus, and/or vertigo
- Diagnosis can be confirmed when one or more of the above criteria occur in association with histologic

Fig. 23-39. Relapsing polychondritis.

Relapsing polychondritis presenting with (A) diffuse and (B) near total redness and swelling of the ear. In this condition, the ear is warm to touch and is painful.

confirmation or by the presence of chondritis in two or more separate anatomic locations with response to steroids and/or dapsone.

- Laboratory findings are nonspecific and include elevated erythrocyte sedimentation rate, mild

Fig. 23-40. Relapsing polychondritis.

A, A mixed inflammatory cell infiltrate is present in relapsing polychondritis, blurring the interface between the cartilaginous plate and dermal collagen; the cartilage has a ragged appearance. **B**, The mixed inflammatory infiltrate is composed of lymphocytes, plasma cells, polymorphonuclear leukocytes, and occasional eosinophils, completely obscuring the interface between the perichondrium and the auricular cartilage, and permeating throughout the cartilage. In both images the cartilage has an eosinophilic appearance with loss of its usual basophilia.

leukocytosis, and normochromic, normocytic anemia; the presence of elevated antineutrophil cytoplasmic antibodies (ANCA) titers has been reported.

- Etiology has not been clearly elucidated; however, there is evidence for an autoimmune process:
 - In association with RP, some patients suffer from other autoimmune disorders (Box 23-2).
- RP is likely a T helper 1 (Th1)-mediated disease as serum levels of interferon (IFN)- γ , interleukin [IL]-12, and IL-2 parallel changes in disease activity, while the levels of Th2 cytokines do not.
- Patients have been known to have factors in their serum that react with cartilage:

BOX 23-2 Autoimmune Diseases Associated with Relapsing Polychondritis

- Systemic lupus erythematosus
 - Rheumatoid arthritis
 - Scleroderma
 - Sjögren syndrome
 - Reiter syndrome
 - Glomerulonephritis
 - Autoimmune thyroid disease
 - Ulcerative colitis
 - Pernicious anemia
 - Raynaud syndrome
- Circulating antibodies to type II collagen found only in cartilage with titers reflecting severity of disease
 - Documentation of immunofluorescent localization of immune complex components at the perichondral-cartilaginous interface have been reported in patients with RP.
 - Patients have immune complexes of immunoglobulins and complement detected in the biopsy specimens taken from inflamed cartilage of involved ears; these findings coupled with the association of RP with an array of known autoimmune systemic diseases lend support to an autoimmune cause.
 - No evidence to support either hereditary or familial predisposition

Pathology**Histology**

- Histologic findings include perichondrial inflammation with a mixed infiltrate of lymphocytes, plasma cells, polymorphonuclear leukocytes, and occasional eosinophils, which blurs the interface between the perichondrium and the auricular cartilage.
- Loss of the usual basophilia in the cartilage, which assumes an eosinophilic appearance with hematoxylin-and-eosin staining.
- At advancing edge of the inflammation there is loss of chondrocytes and destruction of lacunar architecture.
- As cartilage is destroyed, it is replaced by tissue and eventually by fibrous tissue.
- Immunomicroscopic findings, including diffuse granular deposition of IgG and C3 in the perichondrial fibrous tissue, may be demonstrated.

Differential Diagnosis

- External otitis
- Acute (infectious) polychondritis
- Tophaceous gout
- Systemic vasculitides (e.g., granulomatosis with polyangiitis, formerly Wegener granulomatosis)
- Rheumatoid arthritis

Treatment and Prognosis

- Treatment of RP depends on the stage:
 - In the acute stages of disease, corticosteroids are used.
 - In more advanced stages, immunosuppressive agents may be used.
- Prognosis is variable and unpredictable, with some patients having a prolonged course and others suffering from a more aggressive and fulminant disease.
- Death may occur and is most often the result of respiratory tract or cardiovascular system involvement.
- Tocilizumab, a highly effective therapeutic agent for the treatment of rheumatoid arthritis and systemic juvenile idiopathic arthritis, has been reported to be potentially effective therapy not only for rheumatoid arthritis but also for nonrheumatoid arthritis, inflammatory rheumatic diseases, including relapsing polychondritis.
- Cytokine modulation using TNF α blockers, rituximab, anakinra, tocilizumab, and abatacept recently has shown effectiveness in some RP cases, but further substantiation is needed.

TOPHACEOUS GOUT

(Figs. 23-41 and 23-42)

Definition: Disorder of purine metabolism or renal excretion of uric acid, in which there is a precipitation of monosodium urate as deposits (tophi) throughout the body.

Clinical

- One of the more common sites of gouty tophi is the helix of the ear.
- In relationship to the ear, tophi may present as painful skin-covered firm nodules; auricular gouty tophi may be nonpainful.
- Laboratory findings include:
 - Presence of elevated urinary uric acid (hyperuricemia):
 - Measurement of 24-hour urinary uric acid excretion helps in determining whether uric acid overproduction is a cause of the hyperuricemia.
 - Additionally, there is often leukocytosis and increased erythrocyte sedimentation rate.
- In normal body tissues sodium urate is deposited (tophi), but in urine with a lower pH, uric acid is precipitated.
- Gout may occur as an inherited or acquired disease:
 - Primary gout (90% of cases) is an inherited error of metabolism that results from either an

Fig. 23-41. Gouty tophus.

Gouty tophus identified along the helix of the ear appearing as a discrete white nodule that is typically firm to the touch and painful.

enzymatic defect in purine synthesis or a defect in the renal excretion of uric acid.

- Secondary or acquired gout (10% of cases) occurs secondary to disorders that increase the production of uric acid (e.g., leukemias) or decrease excretion of uric acid (e.g., chronic renal failure).

Pathology

Histology

- Gouty tophi are composed of needle-shaped aggregates of urate crystals with a surrounding foreign body giant cell reaction.
- If a diagnosis of gout is suspected, the resected tissue should be fixed in absolute alcohol or any nonaqueous fixative as the urate crystals are water soluble.
- Crystals demonstrate negative birefringence:
 - When a primary color compensator is used in between two polarizing lenses, the crystals will change color from yellow to blue when

Fig. 23-42. Gout.

A, The histology of gout includes the presence of foreign body giant cell reaction typically surrounding needle-shaped crystals. **B,** In this example, a foreign body giant cell reaction is present but the crystals are not readily identifiable as the tissue was not fixed in absolute alcohol or a nonaqueous fixative. **C,** The crystals change color from yellow to blue when polarizing lenses were rotated from parallel to perpendicular.

rotating the polarizing lenses from parallel to perpendicular.

Differential Diagnosis

- Tophaceous pseudogout (Figs. 23-43 and 23-44):
 - Designation of pseudogout is used to describe the presence of calcium pyrophosphate dihydrate crystal deposition in synovial fluid in patients with gout-like symptoms but without sodium urate crystals.
 - Other designations include tumoral calcium pyrophosphate dihydrate deposition disease, chondrocalcinosis, pyrophosphate arthropathy.
 - More recently, this disease has been designated as calcium pyrophosphate dihydrate deposition disease (CPPD).
 - Mutations in the progressive ankylosis homolog human (*ANKH*) gene have been shown to cause familial CPPD.
 - Histologically, tophaceous pseudogout is characterized by:
 - Presence of a variably cellular chondroid-appearing tissue within which is crystalline material
 - Crystalline material appears rhomboid or needle shaped and under polarized light microscopy the crystals showed weak positive birefringence.
- In decalcified material the crystals may be lost.
- A foreign body granulomatous reaction can be seen in association with the crystal deposition.
- Chondroid metaplasia is often present in and around the areas of CPPD deposition.
- There is some evidence to indicate that metaplastic chondrocytes may play a role in the initial precipitation of CPPD crystals.
- Synovial chondrometaplasia may be seen in patients with pyrophosphate arthropathy.
- Metaplastic chondrocytes may show cytologic atypia that could lead to a diagnosis of chondrosarcoma; this is particularly true in decalcified sections from which CPPD crystals are lost.
- In contrast to pseudogout, radiographic calcification in gouty tophi is relatively uncommon.
- In addition, the identification of the specific positive birefringence of the calcium pyrophosphate crystals as seen in tophaceous pseudogout is not a feature seen in gouty tophi.

Fig. 23-43. Calcium pyrophosphate dihydrate deposition disease.

A, Axial T2-weighted image shows a large low signal intensity mass (arrows) in the left infratemporal fossa/TMJ region.
B, On contrast-enhanced T1-weighted image the lesion is partially enhancing.

**Fig. 23-43, cont'd**

C, On precontrast T1-weighted image the lesion has a heterogeneous low to intermediate signal. **D**, Coronal T1 postcontrast shows the heterogeneous mass in the left TMJ infratemporal fossa and middle cranial fossa region. There are erosions of the skull base and expansion in and mass effect on the temporal lobe in the middle cranial fossa. **E**, The lesion was biopsied under CT guidance using a 16-gauge core biopsy needle, and pathologic analysis confirmed calcium pyrophosphate dihydrate. (From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 26-90, p 1592.)

Fig. 23-44. Tophaceous pseudogout.

The histologic features of tophaceous pseudogout include (A) a variably cellular and vaguely lobular chondroid-appearing tissue; (B) crystalline-appearing material with a rhomboid or needle shape within the chondroid tissue (under polarized light microscopy the crystals showed weak positive birefringence, not shown); (C) a foreign body granulomatous reaction (*right*) can be seen in association with the crystal deposition; (D) chondroid metaplasia in and around the areas of CPPD deposition; the chondrocytes may show cytologic atypia.

Treatment and Prognosis

- In acute gout pharmacologic intervention is usually necessary and includes:
 - Nonsteroidal anti-inflammatory drugs (NSAIDs)
 - Oral colchicines
 - Corticosteroids
- Anti-interleukin 1 (IL-1) therapies may also be beneficial in treating acute gout symptoms.
- Resting the painful joint and applying topical ice are helpful in relieving the pain and terminating the attack as quickly as possible.
- In patients with multiple recurrent gout flares or advanced gout the goal of therapy is to prevent disease progression achieved by:
 - Lowering serum urate levels (less than 6.0 mg/dl resulting in mobilization and depletion of crystals to prevent recurrent flares and joint destruction)
 - Allopurinol and febuxostat (uricostatic drugs) are the most widely used approach.
 - Probenecid (uricosuric agent) increases renal excretion of uric acid but is not appropriate for patients who are urate overproducers because of the risk of nephrolithiasis.
 - Pegloticase (uricolytic agent) degrades uric acid into soluble end product, is given intravenously, and is being evaluated in patients for whom conventional therapy is either ineffective or inadequate.

GRANULOMATOSIS WITH POLYANGIITIS (GPA)

(See Section 1, Sinonasal Tract for images.)

Definition: Systemic necrotizing vasculitis that typically involves the kidneys, lung, and upper aerodigestive tract.

- Nomenclature: formerly referred to as Wegener granulomatosis
- Systemic GPA by definition includes kidney involvement.
- Localized GPA involves the sinonasal tract (or other head and neck sites) and/or the lungs.

Clinical

- Otologic involvement by GPA occurs in 20% to 60% of patients with disease of more usual sites.
- Most common otologic manifestations include unilateral or bilateral otitis media (serous or suppurative), perforation of the tympanic membrane, and sensorineural hearing loss; cutaneous involvement of the external ear with perforation of the earlobes and external otitis; facial palsy may occur as the initial manifestation of disease.
- Involvement of the middle ear may occur secondary to nasopharyngeal and sinonasal disease via the eustachian tube or may be due to direct involvement by disease.
- Antineutrophil cytoplasmic autoantibodies (ANCA) should be elevated in the active phase of GPA:
 - Two distinct staining patterns are found: cytoplasmic (c-ANCA) and perinuclear (p-ANCA)
 - GPA is associated with c-ANCA and infrequently with p-ANCA.
 - p-ANCA is more often associated with rheumatic diseases.
 - Patients with generalized GPA have a 60% to 100% c-ANCA positivity; patients with limited GPA have a 50% to 67% c-ANCA positivity.
 - c-ANCA results can be used in establishing a diagnosis of GPA in clinically suspect lesions in which the biopsies are not entirely diagnostic; false positive results are uncommon.
 - c-ANCA titers correlate with disease activity and recurrent disease.
- Proteinase 3:
 - Proteinase-3 (PR3) is a neutral serine proteinase present in azurophil granules of human polymorphonuclear leukocytes and monocyte lysosomal granules.
 - PR3 is the major target antigen of antineutrophil cytoplasmic antibodies with a cytoplasmic staining pattern (c-ANCA) in GPA.
 - ANCA with specificity for PR3 are characteristic for patients with GPA.
 - Patients with GPA demonstrate a significantly higher percentage of mPR3+ neutrophils than healthy controls and patients with other inflammatory diseases.
 - The detection of ANCA directed against proteinase 3 (PR3-ANCA) is highly specific for GPA.
 - ANCA positivity is found only in about 50% of the patients with localized GPA, whereas

PR3-ANCA positivity is seen in 95% of the patients with generalized GPA.

- Pathogenesis of vascular injury in GPA is ascribed to antineutrophil cytoplasmic antibodies directed mainly against PR3.
- Interaction of ANCA with neutrophilic ANCA antigens is necessary for the development of ANCA-associated diseases; ANCA bind to membrane-expressed PR3 and induce full-blown activation in primed neutrophils.
- In patients with GPA, high expression of PR3 on the surface of nonprimed neutrophils is associated with an increased incidence and rate of relapse.
- ANCA-associated vasculitis (AAV) includes GPA, microscopic polyangiitis (MPA), and allergic granulomatous angiitis (AGA):
 - Major target antigens of ANCA associated with vasculitis are PR3 and myeloperoxidase (MPO).
 - PR3-ANCA is the marker for GPA.
 - MPO-ANCA is related to MPA and AGA.
 - ANCA appears to induce vasculitis by directly activating neutrophils.
 - No immunoglobulins or complement components are detected in vasculitis lesions; as such, AAV is called pauci-immune vasculitis.

Pathology

Histologic features are similar to those described in the lungs, kidney, or upper aerodigestive tract (see Section 1, Sinonasal Tract for complete pathologic description and images).

NOTE: Elevation of serum levels of antineutrophil cytoplasmic autoantibodies (ANCA) are of great assistance in those cases in which the diagnosis is suspected but the histology is not definitively diagnostic.

- Special stains for microorganisms, including GMS and AFB, are negative.
- Inflammatory infiltrate shows immunoreactivity for leukocyte common antigen, B-cell markers, and T-cell markers.

Differential Diagnosis

- Other autoimmune or systemic diseases that may involve the middle or inner ear include polyarteritis nodosa and rheumatoid arthritis, which may also involve the middle and inner ear.
- Polyarteritis nodosa is a necrotizing vasculitis of small and medium-sized muscular arteries:
 - Aural-related symptoms include otitis media with effusion.
 - Sensorineural hearing loss may be the initial presentation or after the diagnosis has already be established.

- The histologic diagnosis is dependent on the presence of necrotizing vasculitis.
- Treatment includes corticosteroids and immunosuppressant agents.
- Manifestations of rheumatoid arthritis of the audio-vestibular system includes conductive hearing loss due to involvement of the incudomalleal and incudostapedial articulations; high-dose salicylates in combination with steroids and nonsteroidal anti-inflammatory agents are the preferred treatment.

Treatment and Prognosis

- Combined corticosteroid and immunosuppressive therapy may result in long-term remissions and is

capable of reversing the hearing loss and facial palsy if the diagnosis of GPA can be established and treatment initiated early in the disease course.

- Prognosis for hearing is poor when appropriate treatment is not given in the early stages of the disease.
- Early diagnosis and appropriate treatment are important to prevent irreversible changes in the middle ear and inner ear.

OTOSCLEROSIS (Fig. 23-45)

Definition: Disorder of the bony labyrinth and stapedial footplate that occurs exclusively in humans and is of

Fig. 23-45. Sclerotic phase of otosclerosis.

A, Axial CT image shows a focus of abnormal bone (*arrow*) just anterior to the footplate of the stapes. Note that the bone has almost the same density as the otic capsule. It is also enlarged in size. **B**, Coronal CT image shows the overgrowth of bone impinges on the oval window (*arrow*), causing significant narrowing. The bone has approximately the same density as the otic capsule. **C**, The histologic correlate of the CT findings shows the presence of densely sclerotic bone that resulted in fixation of the stapedial footplate (*arrows*). (*A and B*, From Som PM, Curtin HD: *Head and neck imaging*, ed 5, Philadelphia, 2011, Elsevier, Fig. 19-4, p 1233.)

unknown etiology. Otosclerosis means hardening of the ear and is derived from Greek (*ous*, ear; *skleros*, hard; *osis*, condition); osseous ankylosis (Greek: *ankoulon*, to stiffen).

Synonyms: Chronic metaplastic otitis; progressive otospongiosis

Clinical

- More often affects women than men; usually begins in the second and third decades of life and is slowly progressive
- Prevalence of otosclerosis varies with race and is more common in whites than in blacks, Asians, and Native Americans.
- Otosclerosis primarily causes conductive hearing loss; the extent of the hearing loss directly correlates with the degree of stapedial footplate fixation.
- Otosclerosis usually involves both ears; however, unilateral disease can occur in up to 15% of cases.
- It is not uncommon for patients with otosclerosis also to have vestibular disturbances.
- Radiology:
 - Imaging studies can confirm the clinical consideration of otosclerosis.
 - High-resolution CT is the preferred modality for evaluating middle and inner ear structures, including labyrinth in windows, stapes footplate, cochlear capsule.
- Although many theories regarding the etiology of otosclerosis appear in the literature, the etiology of otosclerosis is unclear:
 - Hereditary factors are often cited as among the causes of otosclerosis, although the mode of inheritance is still uncertain.
 - Family history occurs in more than 50% of cases.
 - The majority of epidemiologic studies on families with otosclerosis suggest an autosomal-dominant mode of inheritance with reduced penetrance of approximately 40%.
 - Genetic linkage studies have demonstrated the presence of six loci (OTSC1, OTSC2, OTSC3, OTSC4, OTSC5, and OTSC7) located on chromosomes 15q, 7q, 6p, 16q, 3q, and 6q, respectively:
 - Although these loci have been mapped, no causative genes have been identified.
 - Disturbed bone metabolism, persistent measles virus infection, autoimmunity, and hormonal and environmental factors also may play contributing roles in the pathogenesis of otosclerosis.
 - Evidence that otosclerosis is derived from the periosteum of the external canal:
 - External layer of the otic capsule arises from periosteal osteoblasts, which produce large numbers of Volkmann canals as well as lamellar bone.

- Main plaque of otosclerosis is a histologic replica of the external layer and seems to arise from similar cells in the periosteum and to follow a defined invasive course into the footplate of the stapes, the basal coil of the cochlea, and the saccule.
- Based on the invasiveness of the plaques apparently derived from the periosteum of the external layer of the otic capsule, some authorities have suggested that otosclerosis is a neoplasm of bone forming a replica of external layer otic capsule tissue (i.e., Volkmann canals and lamellar bone):
 - This suggestion is supported by the marked proliferation of osteoblasts and concomitant production of minicanals seen in the advancing edge of the plaques.

Pathology

Histology

- Initial alterations include resorption of bone around blood vessels.
- Cellular fibrovascular tissue replaces the resorbed bone, resulting in softening of the bone (otospongiosis).
- Immature bone is laid down with continuous active resorption and remodeling.
- New bone is rich in ground substance and deficient in collagen, but, over time, more mature bone with increased collagen and less ground substance is produced, resulting in densely sclerotic bone.
- Process most often begins anterior to the oval window, eventually involving the footplate of the stapes.
- Stapedial involvement causes fixation of the stapes and the inability to transmit sound waves, resulting in conductive hearing loss.
- Similar pathologic involvement of the inner ear may produce sensorineural hearing loss.

Differential Diagnosis

- Paget disease (see below)

Treatment and Prognosis

- Surgical management of the conductive hearing loss caused by stapes fixation (stapedectomy) is the preferred treatment.

PAGET DISEASE OF BONE

(Figs. 23-46 and 23-47)

Definition: Chronic progressive osseous disorder of unknown etiology.

Synonym: Osteitis deformans

Fig. 23-46. Paget disease of the skull and temporal bone.

A, Axial CT image of Paget disease demonstrating thickening of the bony structures with mixed densities of otosclerosis and osteolysis. The changes are symmetric. Thinning of the cochlear capsule is noted bilaterally. The odontoid process protrudes above the foramen magnum to the level of the clivus. **B**, Histologic features include increased new bone characterized by dense irregular masses showing a mosaic pattern. **C**, Higher magnification shows the cement lines of Paget bone as well as scattered osteoclastic giant cells.

Clinical

- Skull and temporal bone involved in approximately 70% of cases:
 - Other sites of involvement include the external auditory canal, tympanic membrane, eustachian tube, ossicles, oval window, round window, internal auditory canal, cochlea, and endolymphatic sac.
- Slightly more common in men than in women; affects about 3% of the population over 40 years of age and as many as 11% of the population over 80 years of age
- Symptoms include hearing loss, tinnitus, and vertigo; the facial nerve is spared.
- Hearing loss is sensorineural, mixed sensorineural, and conductive, and less often only conductive:
 - Hearing losses are progressive and are due to involvement of the osseous portion of the external auditory canal, involvement of the ossicles, and/or involvement of the cochlea and labyrinth.
- Radiology:
 - High-resolution CT of the temporal bone may show mixed appearance of bone thickening and sclerosis.
 - In the temporal bone the disease begins at the petrous apex and progresses inferolaterally; with progression demineralization of the otic capsule may occur.
 - Stapedial footplate may become involved (i.e., thickened), contributing to the (conductive) hearing loss.
 - Frequently, the central skull is also involved.
- Etiology is unknown but consideration has been given for an infectious (viral) cause in genetically predisposed individuals:
 - Measles virus has been reported as playing an important role as an environmental factor in the pathogenesis of Paget disease.

Fig. 23-47. Paget disease of petrous part of the temporal bone around the bony labyrinth.

A, CT scan in Paget disease shows the presence of bone with increase in size. There are demineralization and thinning of the otic capsule (*arrow*). **B**, Coronal image showing thinning of the otic capsule. **C**, The histology includes involvement of the otic capsule characterized by dense, irregular-appearing bone showing a mosaic pattern.

- Interleukin-6 (IL6) is increased in the bone marrow of patients with Paget disease, and measles virus nucleocapsid protein (MVNP) induces IL-6 secretion by pagetic osteoclasts.
- IL-6 plays a critical role in the development of pagetic osteoclasts and bone lesions induced by Paget disease, but the mechanisms regulating IL-6 production by MVNP remain unclear.
- MVNP decreases FoxO3/Sirt1 signaling to enhance the levels of IL-6, which in part mediate MVNP's contribution to the development of Paget disease.

Pathology Histology

- Paget disease is characterized by three histologic phases:
 - First (osteolytic phase): excessive osteoclastic activity resulting in bone resorption
 - Second (mixed or combined phase): new bone formation (osteoblastic activity) predominates over bone resorption (osteoclastic activity) with deposition of new bone next to areas of bone resorption

- Third (osteoblastic phase): increased new bone characterized by dense irregular masses showing a mosaic pattern referred to as cement lines

Differential Diagnosis

- Otosclerosis:
 - Features in Paget disease that assist in separating it from otosclerosis include:
 - Later age of onset
 - Greater sensorineural hearing loss
 - Enlarging calvaria
 - Enlargement and tortuosity of the superficial temporal artery and its anterior branches

Treatment and Prognosis

- Treatment is directed at slowing or preventing progression of disease by suppressing increased bone turnover using oral administration of biphosphonates, which act by decreasing the number of osteoclasts with deposition of structurally normal bone as opposed to deposition of less disordered bone deposition.
- Anti-inflammatory medications are used in relieving bone and joint pain.
- Hearing loss is permanent and cannot be reversed by medical therapy.
- Sarcomatous transformation occurs in approximately 1% of cases and usually transforms to an osteosarcoma:
 - Osteosarcomas arising in Paget disease are highly malignant, with less than 10% 5-year survival rates.

MÉNIÈRE DISEASE

Definition: Idiopathic disorder of the inner ear associated with a symptom complex of spontaneous, episodic attacks of vertigo, sensorineural hearing loss, tinnitus, and a sensation of aural fullness.

Synonyms: Endolymphatic hydrops; idiopathic endolymphatic hydrops; Lermoyez syndrome

Clinical

- Incidence of Ménière disease varies in the literature to include 157 per 100,000 people in England to 46 per 100,000 in Sweden to 7.5 per 100,000 in France.
- Occurs slightly more frequently in women than in men (1.6:1); the peak incidence is in the fifth to seventh decades of life but may occur in children as well as in older individuals (ninth and tenth decades)
- Characterized by a set of symptoms, including fluctuating sensorineural hearing loss, episodes of vertigo, tinnitus, and pressure sensation in the ear:
 - Onset of vertigo is frequently sudden, reaching maximum intensity within a few minutes lasting from an hour or more and either subsiding com-

pletely or continuing as a sensation of unsteadiness for hours to days.

- Etiology is uncertain, although the incidence of Ménière disease is noted to be increased in patients with certain genetically acquired major histocompatibility complexes (MHCs), including HLA B8/DR3 and Cw7, suggesting a possible autoimmune cause.
- Familial occurrence of Ménière disease has been reported, although the role genetic inheritance plays in the mode of transmission is variable.
- Pathogenesis of Ménière disease is distortion of the membranous labyrinth defined as changes in the anatomy of the membranous labyrinth as a consequence of the overaccumulation of endolymph (endolymphatic hydrops) and at the expense of the perilymphatic space:
 - Endolymph, which is produced by the stria vascularis in the cochlea and by cells in the vestibular labyrinth, circulates in a radial and longitudinal fashion.
 - In patients with Ménière disease it is believed that there is inadequate absorption of endolymph by the endolymphatic sac.

Pathology

Histology

- In the early stages of the disease endolymphatic hydrops primarily involves the cochlear duct and saccule but in the later stages the entire endolymphatic system is involved.
- Alterations of the membranous labyrinth include dilatation, outpouching, rupture, and collapse.
- Fistulae (unhealed ruptures) may occur.
- Severe cytoarchitectural and atrophic changes may occur in the sense organs with loss of neurons in the cochlea.

Treatment and Prognosis

- Medical management is the mainstay of therapy; therapy is aimed at reduction of symptoms and is therefore empiric and supportive.
- Optimally, management should resolve the vertigo, tinnitus, and hearing loss.
- Vertigo represents the most debilitating of symptoms, and current management is directed at relieving vertigo.
- Therapy includes prophylaxis via reduction of endolymph accumulation by dietary modification, intermittent dehydration, diuretics, enhancement of the microcirculation of the ear using vasodilators (e.g., betahistidine, adenosine triphosphate, isosorbide, others) and reduction in immune reactivity using steroids, immunoglobulin, and allergy therapy.
- Symptomatic therapies include antivertiginous medications, antiemetics, sedatives, antidepressants, and psychiatric management.

- Improvement in 60% to 80% of patients has been reported.
- Surgical treatment is reserved for those patients who have failed medical management (approximately 10% of patients) and includes shunting or decompression of the endolymphatic sac, labyrinthectomy, or sectioning of the vestibular nerve.
- Combined corticosteroid and immunosuppressive therapy may result in long-term remissions and is

capable of reversing the hearing loss and facial palsy if the diagnosis can be established and treatment initiated early in the disease course.

Neoplasms of the Ear and Temporal Bone

CLASSIFICATION OF NEOPLASMS OF THE EAR AND TEMPORAL BONE

BOX 24-1 Classification of Neoplasms of the Ear and Temporal Bone

I. External Ear

A. Benign

- Epithelial/neuroectodermal/mesenchymal
 - Keratoacanthoma
 - Ceruminous gland neoplasms
 - Seborrheic keratoses
 - Squamous papilloma
 - Melanocytic nevi
 - Dermal adnexal neoplasms
 - Pilomatrixoma (calcifying epithelioma of Malherbe)
 - Neurilemmoma/neurofibroma
 - Osteoma; chondroma
 - Hemangioma
 - Others

B. Malignant

- Epithelial/neuroectodermal/mesenchymal
 - Basal cell carcinoma
 - Squamous cell carcinoma and variants (Verrucous carcinoma, spindle cell squamous carcinoma, adenoid squamous cell carcinoma, others)
 - Ceruminous gland adenocarcinomas
 - Malignant melanoma
 - Merkel cell carcinoma
 - Atypical fibroxanthoma
- Others

II. Middle and Inner Ear

A. Benign

- Epithelial
 - Middle ear adenoma
 - Middle ear papilloma
 - Others
- Neuroectodermal/mesenchymal
 - Jugulotympanic paraganglioma
 - Meningioma
 - Acoustic neuroma
 - Others

B. Malignant

- Epithelial
 - Middle ear adenocarcinoma
 - Primary squamous cell carcinoma
- Neuroectodermal/mesenchymal
 - Endolymphatic sac papillary tumor
 - Rhabdomyosarcoma
 - Vascular (angiosarcoma; Kaposi sarcoma)
 - Lymphoproliferative (malignant lymphoma; plasmacytoma)
- Secondary tumors

BENIGN NEOPLASMS OF THE EXTERNAL EAR

KERATOACANTHOMA (KA) (Fig. 24-1)

Definition: Solitary squamous epithelial neoplasm believed to arise from hair follicles, frequently occurring on sun-exposed areas of the skin and characterized by rapid development followed by involution and spontaneous regression.

NOTE: Some experts believe that solitary keratoacanthomas represent squamous cell carcinoma with a real but limited ability to metastasize.

Clinical

- No gender predilection; most frequently seen in the sixth to seventh decades of life
- Frequently develop on sun-exposed skin:
 - Majority occur on the face (most commonly on the cheek and nose)
 - Approximately 10% occur on the external ear (pinna); occasionally may occur on the lips
- Usually a solitary lesion but multiple KAs occur
- Initially the lesion appears as an erythematous papule or may resemble a wart but over a 1- to 2-month period undergoes rapid enlargement to appear as an exophytic or dome-shaped nodule with a central keratin crater measuring from 1 to 3 cm in diameter.
- Typically arise rapidly (6 to 8 weeks) followed by a stationary period lasting up to several months which in turn is followed by involution with spontaneous regression ultimately leading to (crateriform) scar.
- Whole growth process may be seen over periods of several months up to a year.
- Etiology is unknown but is probably the result of actinic damage.

Fig. 24-1. Keratoacanthoma.

A, Keratoacanthoma characterized by the presence of a well-differentiated squamous epithelial proliferation with characteristic cup-shape and with a central keratin plug. **B**, In the depth of the lesion the epithelial proliferation is composed of nests of large keratinocytes with a “glassy”-appearing or eosinophilic cytoplasm and prominent intercellular bridges. **C**, A variable chronic inflammatory infiltrate may be seen composed of mature lymphocytes, histiocytes, eosinophils, and polymorphonuclear leukocytes with neutrophilic intraepithelial “microabscesses.”

- Multiple and syndromic keratoacanthomas exist and may occur in patients with genetic predisposition.
- Less common variants include:
 - Giant keratoacanthoma:
 - Grows rapidly and reaches a size of 5 cm or more
 - May cause destruction of underlying tissues
 - Spontaneous involution occurs after several months.
 - Most common sites are the nose and eyelids.
 - Keratoacanthoma centrifugum marginatum:
 - May reach 20 cm in diameter
 - No tendency to spontaneous involution
 - Peripheral extension with raised, rolled border and central atrophy
 - Most common sites are dorsa of hands and legs
- Subungual keratoacanthoma:
 - Aggressive behavior that fails to regress spontaneously
 - Destructive growth in distal portion under a fingernail
- Described as part of Muir-Torre syndrome, which is characterized by:
 - Multiple neoplasms of the skin, including those with sebaceous differentiation and internal (visceral) neoplasms, the most common of which are of colonic origin (adenocarcinoma, adenoma)
 - In Muir-Torre syndrome, KAs may be one of multiple cutaneous lesions or represent the only type of cutaneous tumor present in this syndrome.

Pathology

Gross

- Early lesions appear as an erythematous papule or a wart-like growth.
- Mature lesions are elevated and firm with an exophytic or dome-shaped appearance characterized by skin-colored edges and a central cavity or crater filled with keratin debris.
- Measures from 1 to 3 cm and occasionally may reach sizes measuring up to 5 cm

Histology

- Cup-shaped symmetric lesion with deep bulbous lobules of squamous cells
- Early lesion shows hyperkeratosis, parakeratosis, acanthosis with hypergranulosis, and papillomatosis with strands of atypical and dyskeratotic keratinocytes forming a central crater extending into the epidermis.
- Mature lesions form a crater filled with hyper- and orthokeratotic material, below which is the epithelial proliferation composed of nests of large keratinocytes with a “glassy”-appearing or eosinophilic cytoplasm and prominent intercellular bridges.
- Dyskeratosis and squamous pearl formation are commonly seen.
- Transition area between the adjacent squamous epithelium and the hyperplastic epithelium forming the crater is noted by the formation of “shoulders,” a characteristic low-power finding.
- A variable chronic inflammatory infiltrate may be seen in the dermis surrounding the lesion composed of mature lymphocytes, histiocytes, eosinophils, and polymorphonuclear leukocytes; neutrophilic intraepithelial “microabscesses” are often seen.
- Vascular and perineural invasion may be seen.
- With time the lesion involutes and is characterized by regression of the epithelial proliferation, a shallower central crater, granulation tissue proliferation, and fibrosis of the dermis.

Differential Diagnosis

- Benign keratosis
- Seborrheic keratosis, including inverted follicular keratoma
- Squamous cell carcinoma:
 - Differentiation from squamous cell carcinoma is made on the basis of the overall architecture because cytologic atypia is not a reliable criterion for differentiating KA from squamous cell carcinoma.
 - Differentiation can be extremely difficult especially if less than adequate biopsy material is provided (e.g., from the central aspects of the tumor).

- No reliable immunohistochemical staining and/or molecular biologic analyses allowing for differentiating KA from squamous cell carcinoma

Treatment and Prognosis

- Complete surgical excision is the preferred treatment and is curative.
- Despite the result of involution and regression, keratoacanthomas should be treated surgically for the following reasons:
 - Cosmetic considerations
 - Allow for the best overall architectural evaluation to confirm the diagnosis and help differentiate from a squamous cell carcinoma
 - Treatment would be the same for a well-differentiated squamous cell carcinoma in this location.
 - A small percentage of cases may recur.
- Keratoacanthomas have been reported to metastasize; however, the metastases have been squamous cell carcinomas, suggesting that the primary tumors may have also been squamous cell carcinomas.
- Presence of vascular and/or perineural invasion are not findings indicative of malignancy.
- Diagnosis of KA as opposed to squamous cell carcinoma can be made if certain conditions are met, including:
 - Clear-cut clinical description of the lesion is provided.
 - Clinical history of rapid evolving lesion with KA as the primary clinical diagnosis
 - No history of immunosuppression
 - Adequate biopsy provided allowing for complete visualization of the lesion
 - Classic histologic findings are identified.
 - In the absence of these conditions a diagnosis of squamous cell carcinoma is likely.

BENIGN CERUMINAL GLAND NEOPLASMS

Definition: Benign tumor of cerumen-secreting modified apocrine glands (ceruminal glands) located in the external auditory canal.

General Comments

- Ceruminal gland tumors arise from the cerumen-secreting modified apocrine glands (ceruminal glands) in the external auditory canal:
 - Ceruminal glands are located in the dermis of the cartilaginous (inner) portion (outer third) of the external auditory canal.

BOX 24-2 Classification of Ceruminal Gland Neoplasms**Benign Ceruminal Gland Tumors**

- Ceruminal gland adenoma (ceruminoma)
- Pleomorphic adenoma
- Syringocystadenoma papilliferum

Malignant Ceruminal Gland Tumors

- Ceruminal gland adenocarcinoma
- Adenoid cystic carcinoma
- Mucoepidermoid carcinoma

- In general, ceruminal gland neoplasms are uncommon but represent one of the more common tumors of the external auditory canal.
